1. Abstract

NOAA Atlas 14 contains precipitation frequency estimates for the United States and U.S. affiliated territories with associated 90% confidence intervals and supplementary information on temporal distribution of annual maxima, analysis of seasonality and trends in annual maximum series data, etc. It includes pertinent information on development methodologies and intermediate results. The results are published through the Precipitation Frequency Data Server (http://hdsc.nws.noaa.gov/hdsc/pfds).

The Atlas is divided into volumes based on geographic sections of the country. The Atlas is intended as the U.S. Government source of precipitation frequency estimates and associated information for the United States and U.S. affiliated territories.

2. Preface to Volume 4

NOAA Atlas 14 Volume 4 contains precipitation frequency estimates for selected durations and frequencies with 90% confidence intervals and supplementary information on temporal distribution of annual maxima, analysis of seasonality and trends in annual maximum series data, etc., for the Hawaiian Islands. The results are published through the Precipitation Frequency Data Server (http://hdsc.nws.noaa.gov/hdsc/pfds).

NOAA Atlas 14 Volume 4 was developed by the Hydrometeorological Design Studies Center within the Office of Hydrologic Development of the National Oceanic and Atmospheric Administration's National Weather Service. Any use of trade names in this publication is for descriptive purposes only and does not imply endorsement by the U.S. Government.

Citation and version history. This documentation and associated artifacts such as maps, grids, and point-and-click results from the PFDS are part of a whole with a single version number and can be referenced as:

Sanja Perica, Deborah Martin, Bingzhang Lin, Tye Parzybok, David Riley, Michael Yekta, Lillian Hiner, Li-Chuan Chen, Daniel Brewer, Fenglin Yan, Kazungu Maitaria, Carl Trypaluk, Geoffrey Bonnin (2011). NOAA Atlas 14 Volume 4 Version 3, *Precipitation-Frequency Atlas of the United States*, *Hawaiian Islands*. NOAA, National Weather Service, Silver Spring, MD.

The version number has the format P.S where P is a primary version number representing a number of successive releases of primary information. Primary information is essentially the data. S is a secondary version number representing successive releases of secondary information. Secondary information includes documentation and metadata. S reverts to zero (or nothing; i.e., Version 2 and Version 2.0 are equivalent) when P is incremented. When new information is completed and added (such as draft documentation) without changing any prior information, the version number is not incremented.

The primary version number is stamped on the artifact or is included as part of the filename where the format does not allow for a version stamp (for example, files with gridded precipitation frequency estimates). All location-specific output from the PFDS is stamped with the version number and date of download.

Table 2.1 lists the version history associated with the NOAA Atlas 14 Volume 4 precipitation frequency project and indicates the nature of changes made.

Table 2.1. Version history of the NOAA Atlas 14 Volume 4.

Version no.	**Date**	**Notes**
Version 1.0	September 2008	Draft data used in peer review
Version 2.0	March 2009	Data released
Version 2.0	May 2009	Documentation released
Version 2.1	January 2010	Minor edits in documentation
Version 3.0	June 2011	Estimates: scaling factors for n-minute durations adjusted; temporal distribution files updated (see Appendix A.10 for more details). Documentation: Section 5 rewritten to reflect updated PFDS, order of appendices changed to match format of Volumes 5 and 6, minor changes to text.

3. Introduction

3.1. Objective

NOAA Atlas 14 Volume 4 provides precipitation frequency estimates for the Hawaiian Islands. The Atlas provides precipitation frequency estimates for 5-minute through 60-day durations at average recurrence intervals of 1-year through 1,000-year. The estimates and associated bounds of 90% confidence intervals are provided at 15-arc seconds resolution. The Atlas also includes information on temporal distributions for annual maxima data used in frequency analysis and seasonal information on heavy precipitation. In addition, the potential effects of climate change as trends in historic annual maximum series were examined.

The information in NOAA Atlas 14 Volume 4 supersedes precipitation frequency estimates for the Hawaiian Islands contained in the following publications:

a. *Technical Paper No. 43, Rainfall-Frequency Atlas of the Hawaiian Islands for Areas to 200 Square Miles, Durations to 24 Hours, and Return Periods from 1 to 100 Years* (U.S. Weather Bureau, 1962);

b. *Technical Paper No. 51, Two- to Ten-Day Rainfall for Return Periods of 2 to 100 Years in the Hawaiian Islands* (U.S. Weather Bureau, 1965).

3.2. Approach and deliverables

Precipitation frequency estimates have been computed for a range of frequencies and durations using a regional frequency analysis approach based on L-moment statistics calculated from annual maximum series. This section provides an overview of the approach; greater detail is provided in Section 4.

The annual maximum series used in the precipitation frequency analysis were extracted from precipitation measurements recorded at daily, hourly and n-minute time intervals from various sources. The table in Appendix A.1 gives detailed information on all stations whose data were used in the frequency analysis. The annual maximum series data were screened for erroneous measurements. The 1-day and 1-hour annual maximum series data were also analyzed for potential trends (Appendix A.2).

To support the regional frequency analysis approach, homogeneous regions with respect to annual maximum series precipitation characteristics were delineated. Adjustments were made in the definition of regions based on statistical tests and underlying climatology. Regional estimates of relevant L-moment statistics, regional homogeneity measures and regional growth factors for hourly and daily durations are shown in Appendices A.3, A.4 and A.5, respectively.

A variety of probability distribution functions were examined for each region and duration and the most suitable distribution was selected based on the results of goodness-of-fit tests. AMS-based precipitation frequency estimates for a selected distribution were determined at each station based on the mean of the annual maximum series at the station and the regionally determined higher order L-moment ratios for each duration. Partial duration series-based precipitation frequency estimates were calculated indirectly from AMS results.

A Monte-Carlo simulation approach was used to produce upper and lower bounds of the 90% confidence intervals for the precipitation frequency estimates. Due to the small number of stations recording data at less than 1-hour intervals, precipitation frequency estimates and confidence intervals for durations below 1-hour (n-minute durations) were computed using an average ratio between the n-minute and 1-hour frequency estimates as determined based on available data.

Gridded estimates of precipitation magnitude-frequency relationships and 90% confidence intervals were determined based on the mean annual maxima grids and the regionally determined higher order L-moment ratios. The mean annual maxima grid for each duration was derived from at-station estimates of mean annual maxima using PRISM interpolation methodology (Appendix A.6). The grid of quantiles for each successive average recurrence interval or annual exceedance probability was then derived in an iterative process using the Cascade, Residual Add-Back (CRAB) spatial interpolation procedure (Section 4.6). The resulting grids were examined and adjusted in cases where inconsistencies occurred between durations and frequencies.

Both spatially interpolated and point estimates were subject to external peer reviews (see Section 6 and Appendix A.7). Based on the results of the peer review, adjustments were made where necessary.

Temporal distributions of annual maximum series data for selected durations were calculated for each homogeneous region delineated in the precipitation frequency analysis; they are shown in Appendix A.8. The seasonality analysis was done by tabulating the number of precipitation amounts exceeding precipitation frequency estimates for several selected threshold frequencies in each region (Appendix A.9).

NOAA Atlas 14 Volume 4 precipitation frequency estimates for any location in the project area are available in a variety of formats through the Precipitation Frequency Data Server (PFDS) at http://hdsc.nws.noaa.gov/hdsc/pfds (via a point-and-click interface); more details are provided in Section 5. Additional types of results and information available there include:

- ASCII grids of partial duration series-based and annual maximum series-based precipitation frequency estimates and related confidence intervals for a range of durations and frequencies with associated Federal Geographic Data Committee-compliant metadata;
- cartographic maps of partial duration series-based precipitation frequency estimates for selected frequencies and durations;
- annual maximum series used in the analysis;
- temporal distributions;
- seasonality analysis.

Cartographic maps were created to serve as visual aids and are not recommended for estimating precipitation frequency estimates. Users are advised to take advantage of the PFDS interface or the underlying ASCII grids for obtaining precipitation frequency estimates. Precipitation frequency estimates from this Atlas are estimates for a point location and are not directly applicable for an area.

4. Precipitation frequency analysis

4.1. Project area

The project area, shown in Figure 4.1.1, includes the eight largest islands at the southeastern end of the Hawaiian Islands archipelago. These islands are (from the northwest to southeast): Niihau, Kauai, Oahu, Molokai, Lanai, Kahoolawe, Maui, and Hawaii. In this project, the island names are spelled without the separator (or 'okina). The island of Hawaii is by far the largest, and is often called the "Big Island" to avoid confusion with the state as a whole.

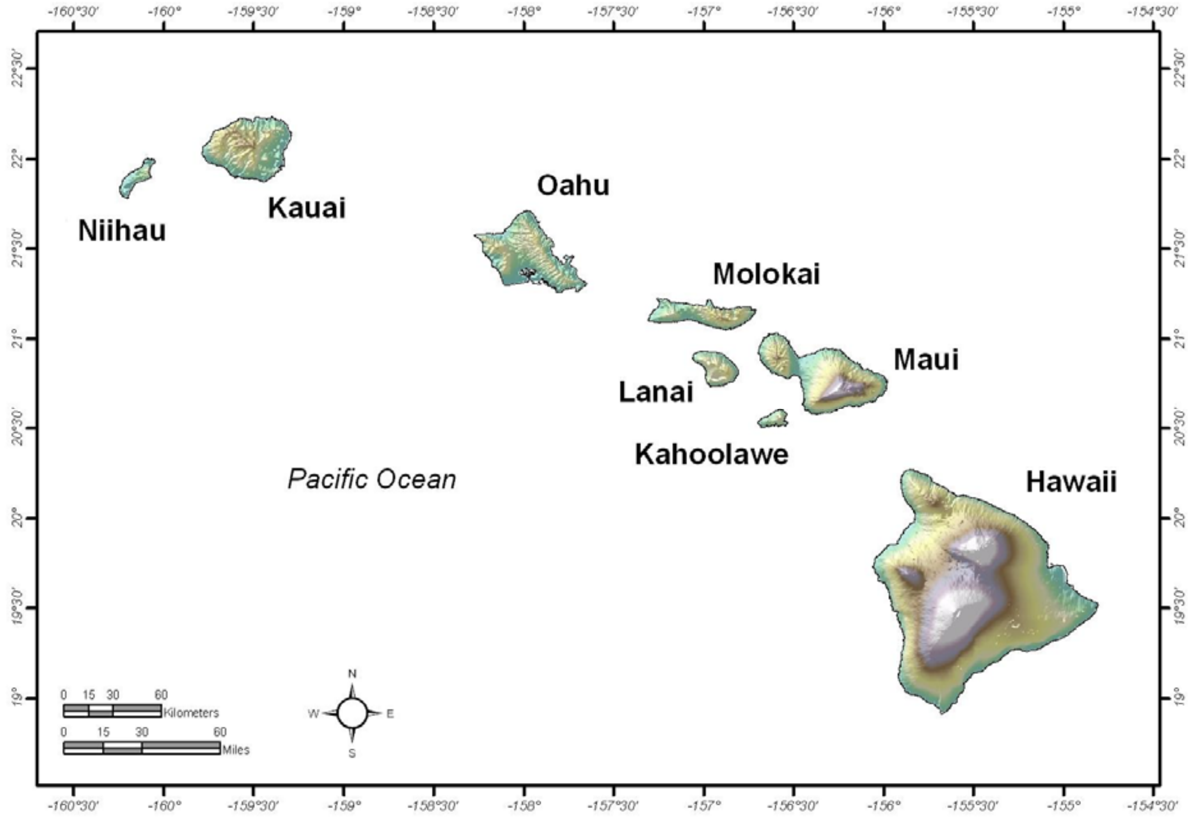

Figure 4.1.1. Project area for NOAA Atlas 14 Volume 4.

Climatology of heavy precipitation. Extreme precipitation over the Hawaiian Islands is a well-documented phenomenon with several locations on the islands holding U.S. precipitation records at longer durations. A combination of Pacific moisture with rapidly changing topography provides a wide range of precipitation in relatively short distances. Two distinct seasons are recognized in the regime of Hawaii: a summer season of five months (May through September) and a winter season of seven months (October through April). Summer is the drier season in terms of average monthly rainfall, except on the Kona Coast (leeward coast) of the Big Island. During this season, the most prominent dynamic mechanism is the easterly trade winds being forced upslope leading to orographically enhanced rainfall on nearly every island's eastern mountain range. The highest elevations on the islands, such as Mauna Kea and Mauna Loa on the Big Island, are too high to be affected by the trade winds and are some of the driest locations in Hawaii. An inversion on the upper boundary of the trade winds prevents the moist, unstable air from reaching these higher elevations. As a result, moisture flow is redirected around the higher peaks leading to extreme precipitation on either side. The leeward sides of the mountains are protected from the trade winds and are less prone to the frequent precipitation events. However, occasionally land-sea circulations are strong enough to trigger rainfall there enhanced by the topography.

Major storms and torrential rains occur most frequently in the winter season between October and April, during which the trade winds retreat south of Hawaii. These events are primarily associated with Kona lows, cold fronts, and tropical storms or hurricanes. Kona lows are subtropical cyclones that form during the cool season and usually occur two or three times a year and may affect the islands for several days. Cold fronts are more frequent (as many as six to eight may sweep across the islands, especially in the northern islands), but do not last as long as the Kona storms. Hurricanes and tropical storms are less common than Kona lows, but are similar in that they do not approach from one common direction. Unlike cold fronts and Kona storms, hurricanes and tropical storms are not limited to the winter season. They are likely to occur during the last half of the year, from July through December. With the exception of the cold fronts, storms take various paths across the islands bringing heavy rainfall to any portion of the islands. These storms provide interior and leeward locations along mountain sides with the opportunity for significant rainfall.

4.2. Data

4.2.1. Data sources

The annual maximum series used in the precipitation frequency analysis were extracted from precipitation measurements recorded at 1-day, 1-hour, 15-minute and various n-minute time intervals from several sources. The National Weather Service (NWS) Cooperative Observer Program's stations obtained from National Oceanic and Atmospheric Administration's (NOAA) National Climatic Data Center (NCDC) were the primary data source. Table 4.2.1 shows all potential data sources we were able to identify, grouped based on the data reporting intervals (data type), with links to web sites from which the data were downloaded when applicable. The table shows the total number of stations obtained from each source and the number of stations that passed all screening criteria and were used in the frequency analysis (numbers shown in this table are after some stations were merged; see Sections 4.2.2. and 4.4).

Table 4.2.1. Data sources with dataset names grouped by reporting interval and links to web sites from which the data were downloaded when applicable (web links as of May 2009). Also shown are total number of stations and number of stations used in frequency analysis per source.

Data reporting interval	**Source of data and data set name**	**Number of stations**	
		total	**used**
1-day	NCDC: *TD3200* and *TD3206* (http://cdo.ncdc.noaa.gov/CDO/dataproduct)	560	263
	Hawaii State Climate Office: monthly maxima	236	89

TOTAL		**1146**	**428**

4.2.2. Initial data screening

Initial data screening included examination of geospatial data, screening for duplicate stations, and merging data from two or more nearby stations. Further data screening for sufficient number of years with usable data and data quality control were done on annual maximum series extracted from precipitation records for a range of durations (see Section 4.4).

Locations of daily stations used in the project are shown in Figure 4.2.1 and locations of hourly and n-minute stations are shown in Figure 4.2.2. Also shown in the figures are “supplemental stations” used to anchor spatial patterns during interpolation (see Sections 4.5.3 and 4.6). More detailed information on each station used in the frequency analysis is given in Appendix A.1. The tables in the appendix are organized by data type and for each station include its identification number, name, island name, data source, latitude, longitude, elevation, period of record and regional assignment needed for regional frequency analysis (see Section 4.5.2). Identification numbers shown in the table were assigned internally and, except for NCDC stations, do not match identification numbers assigned by agencies that provided the data.

Geospatial data. Latitude, longitude and elevation data for all stations used in the project were screened for errors. In a few cases, it was necessary to re-locate stations that plotted in the ocean or were severely mismatched according to elevation differences with a digital elevation model. Changes to coordinates were kept to a minimum. One station was deleted because its proper location could not be identified. The tables in Appendix A.1 contain the coordinates used in this project.

Nearby stations. For this project, nearby stations were defined as stations located within 1.5-mile distance and no more than 500-feet difference in elevation. They were considered for merging to increase record lengths. Double-mass curve analysis and *t*-tests at the 90% confidence level were used to ensure that the annual maximum series of stations considered for merging were from the same population. Forty-two sets of daily stations (either in pairs or sets of three) and ten sets of hourly stations that passed the t-test were merged. Station metadata shown in Appendix A.1 is after merging was completed.

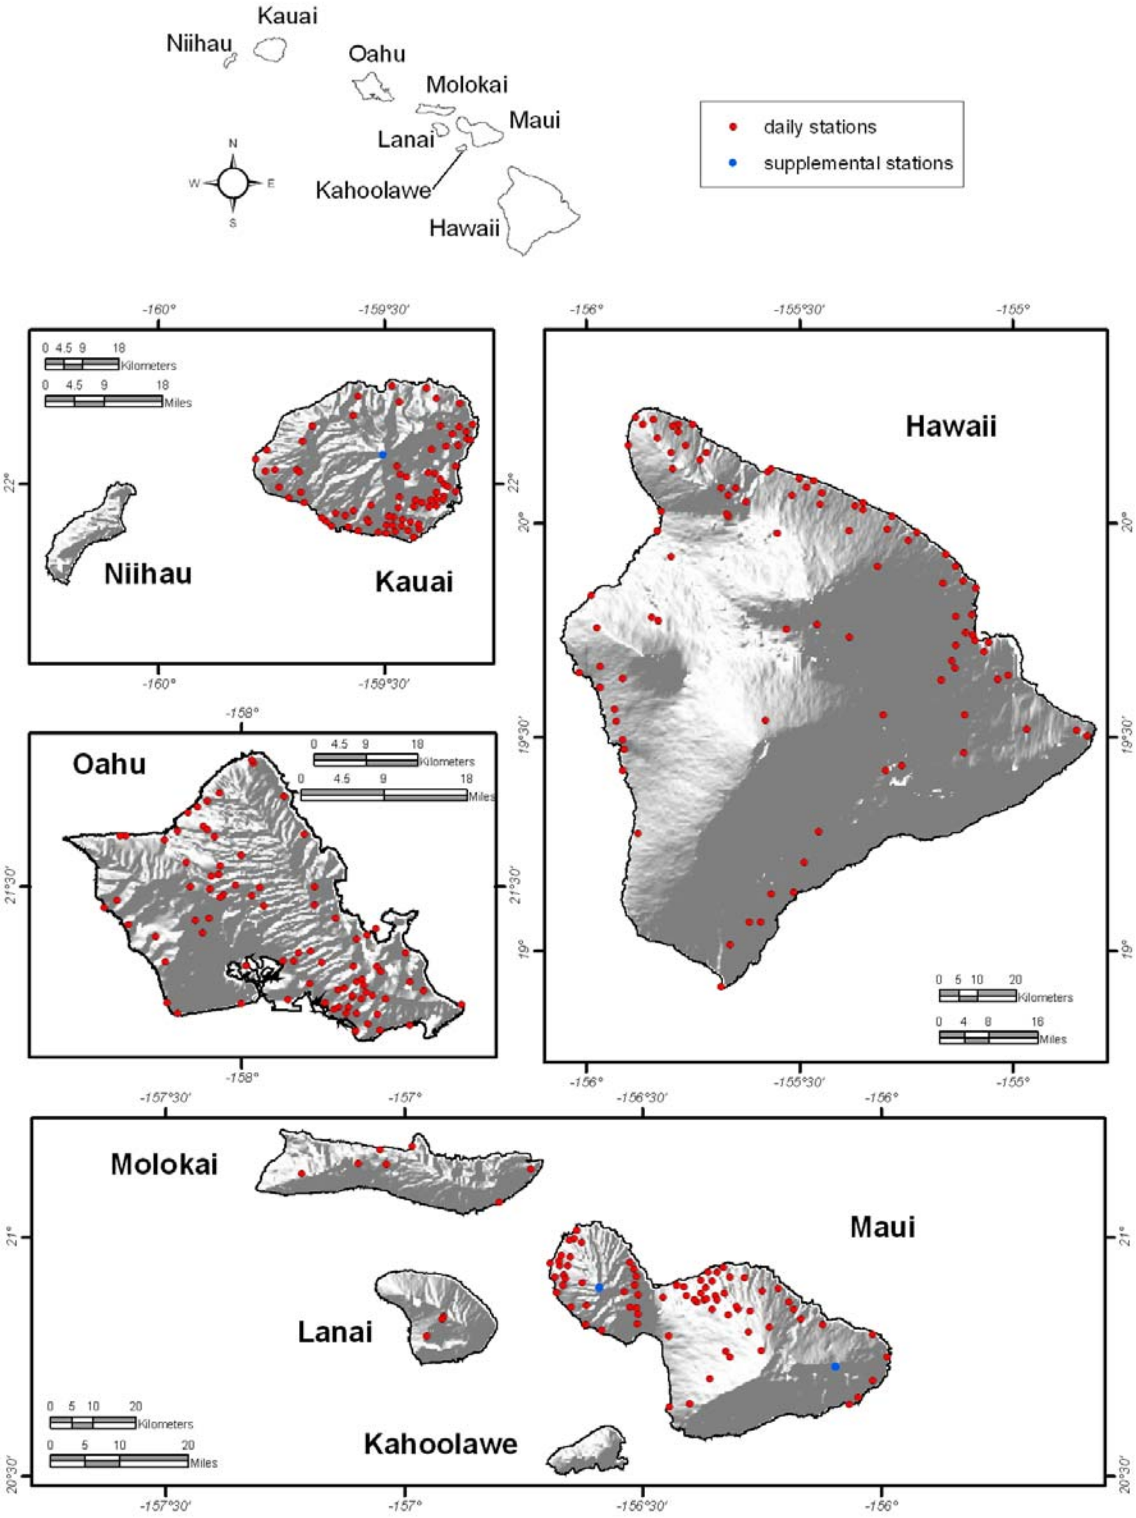

Figure 4.2.1. Map of daily and supplemental daily stations.

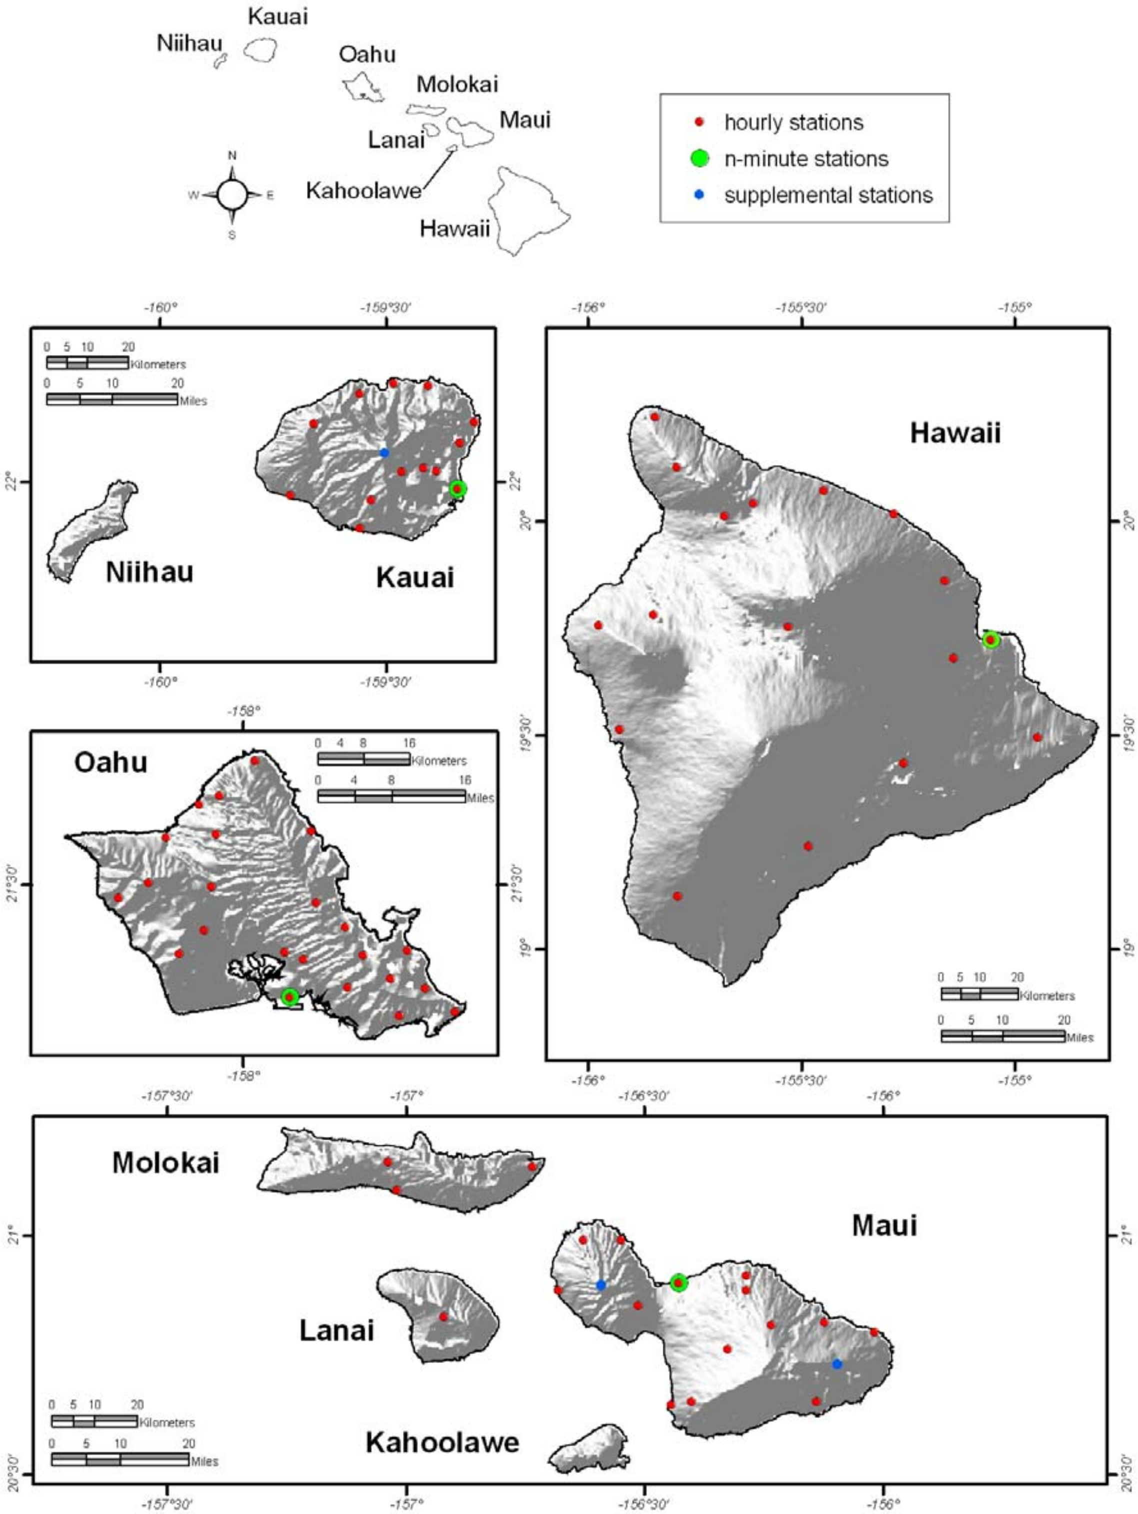

Figure 4.2.2. Map of hourly, supplemental hourly and n-minute stations.

4.3. Annual maximum series extraction

4.3.1. Series selection

Precipitation frequency estimates can be obtained by analyzing annual maximum series (AMS) or partial duration series (PDS). AMS are constructed by extracting the highest precipitation amount for a particular duration in each successive year of record, whether the year is defined as a calendar or water year. Water year, starting on October 1 of the previous calendar year and ending on September 30, was used in this project. AMS inherently exclude other heavy precipitation cases that occur in the same year, regardless of whether they exceed maxima of other years. PDS include all amounts for a specified duration at a given station above a pre-defined threshold regardless of year and can include more than one event from any particular year. Differences in magnitudes of corresponding frequency estimates from the two series are negligible for average recurrence intervals greater than about 15 years, but notable at smaller average recurrence intervals (see Section 4.5.1 for more details). These differences may be important depending on the application. Because PDS can include more than one event in any particular year, the results from a PDS-based analysis are regarded as more suitable for designs based on more frequent events.

In this project, only AMS were directly extracted from the data. AMS-based precipitation frequency estimates where then converted to PDS-based frequency estimates using Langbein's formula (see Sections 4.5.1 and 4.5.4). The AMS were extracted at each station for a range of durations varying from 5 minutes to 60 days. AMS for the 24-hour duration were compiled from daily and hourly records; 2-day through 60-day AMS were compiled only from daily records. Hourly data were also used to compile AMS for 60-minute through 12-hour durations. Stations from the Hawaii State Climate Office database with only monthly maxima were used to compile AMS for the 24-hour duration only. AMS for durations from 5-minute to 60-minute were compiled from n-minute datasets.

4.3.2. Criteria for extraction

The procedure for developing an AMS from a dataset employs specific criteria designed to extract only reasonable maxima if a year is incomplete or has accumulated data. Accumulated data occurred in some daily records where observations were not taken daily, so recorded numbers represent accumulated amounts over extended periods of time. Since the precipitation distribution over the period is unknown, the total amount was distributed equally among the days of the accumulated series during the extraction process for consideration as maxima. All annual maxima that resulted from accumulated data were flagged and went through additional screening to ensure that the incomplete data did not result in erroneously low maxima (see Section 4.4.2).

The criteria for AMS extraction used in this project was designed to exclude maxima if there were too many missing or accumulated data during the year and more specifically during critical months when rainfall maxima were most likely to occur ("wet season"). The wet seasons for extraction purposes were assigned by inspecting histograms of annual maxima for the 1-day and 1-hour durations. The final wet seasons were allocated based on homogeneous regions developed for frequency analysis. The development and delineation of the homogeneous regions for frequency analysis is discussed in Section 4.5.2 and shown in Figures 4.5.1 and 4.5.2. Wet seasons assigned to daily and hourly regions are shown in Tables 4.3.1 and 4.3.2, respectively.

Table 4.3.1. Wet season for each of the 28 daily regions.

Daily region	Wet season
5, 17, 19, 20, 21, 22	October - April
4, 6, 7, 14, 18, 26, 27	October - May
23, 24	October - September
9	September - May
8, 10, 11, 16, 28	August - April
1, 2, 12, 13	August - May
15	July - April
3, 25	November - April

Table 4.3.2. Wet season for each of the 11 hourly regions.

Hourly region	Wet season
8, 9	October - April
1, 5	September - April
2, 3, 4, 7	September - May
6, 10, 11	August - May

The flowchart below (Figure 4.3.1 with Table 4.3.3) depicts the AMS extraction criteria for all durations. Various thresholds for acceptable amounts of missing or accumulated data were applied to the year and wet season based on duration. For example, regarding accumulations for the 10-day duration, if a year had more than 66% of days with accumulated data, then the maximum for that year for 10-day duration was (conditionally) rejected. If the year had between 33% and 66% of days with accumulated data, then it was further screened by assessing the lengths of the accumulated periods. If more than 66% of the accumulated data came from accumulation periods of 7 days or more, the number was rejected. If the year had less than 33% of accumulated data, the extracted maximum was passed to another set of criteria for accumulations during its wet season, etc.

The extracted maximum amount for a given year had to pass through all of the criteria in Figure 4.3.1 to be accepted. All rejected maxima were compared with the accepted maxima; if they were higher than 95% of the maxima at that station, then they were kept in the record. Also, if a 1-day observation was higher than any other accumulated amount in a year, then it was retained. For the 1-day duration, annual maxima were also extracted from the Hawaii State Climate Office's datasets that contained records of only 1-day monthly maxima. Data quality flags were assigned to accepted and rejected maxima to assist in further quality control of AMS described in Section 4.4.

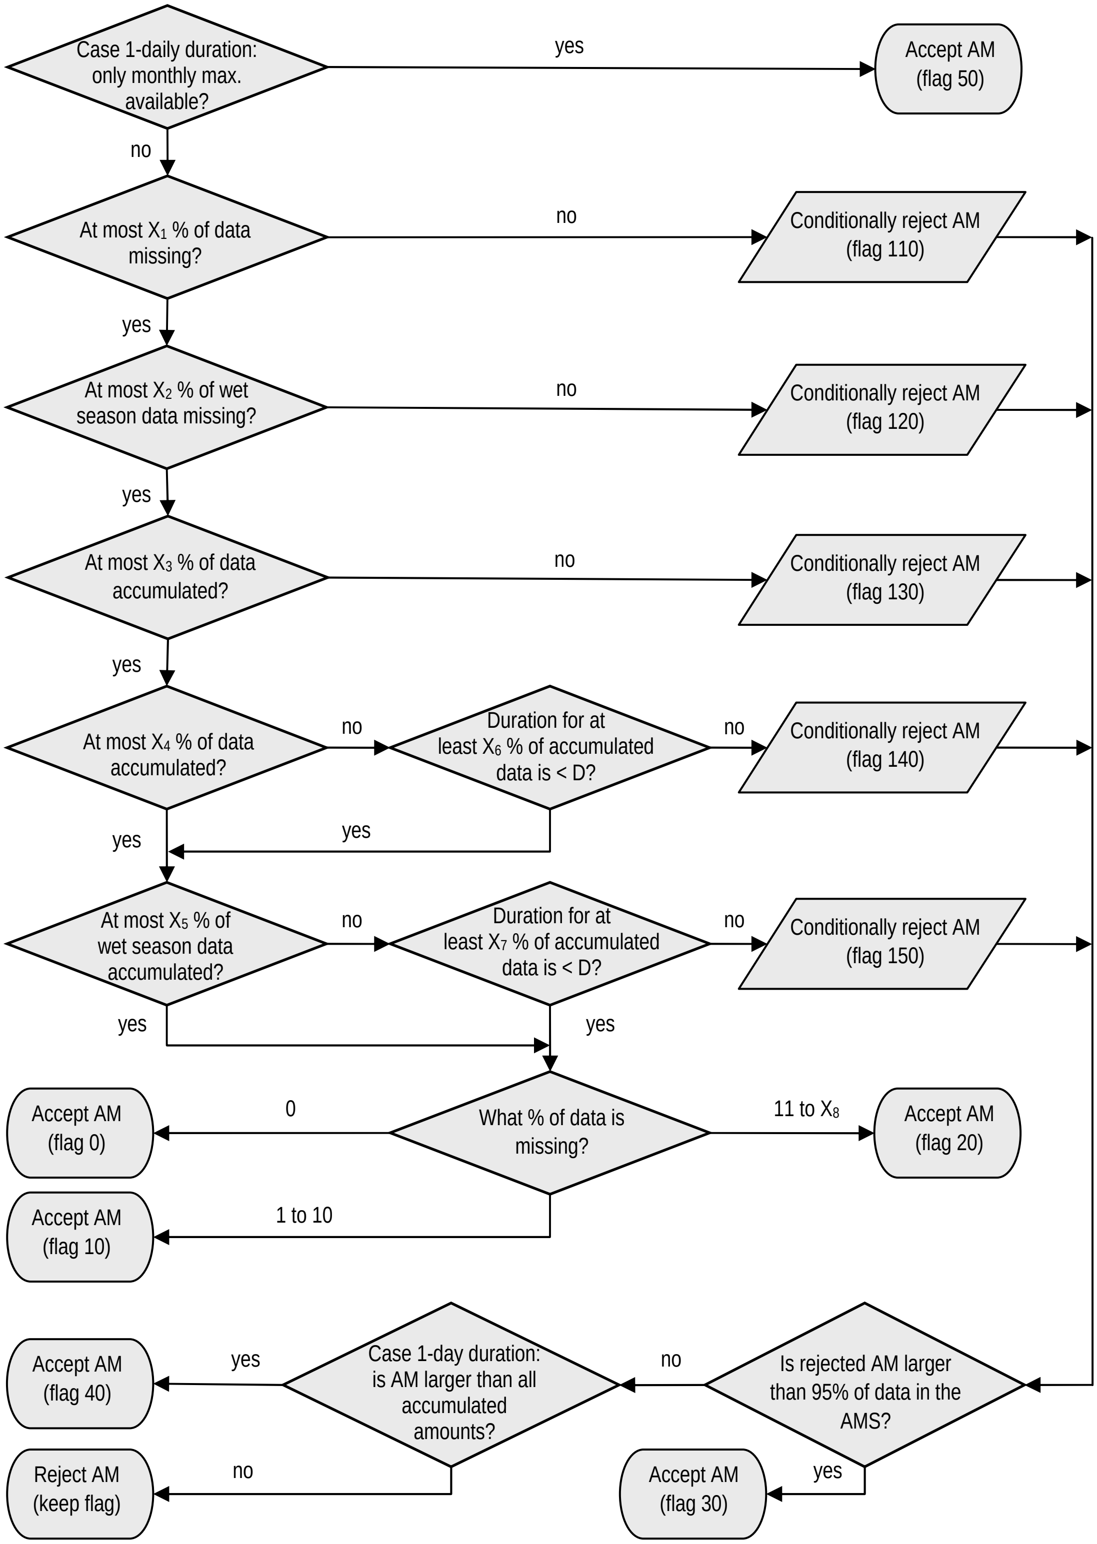

Figure 4.3.1. Flowchart depicting the criteria used to extract annual maxima. Data quality flags were assigned based on acceptance and rejection. Table 4.3.1 shows the parameter values (X_i and D) for each criterion and duration.

Table 4.3.3. Specific parameters applied during annual maximum extraction for all hourly and daily durations (as shown in Figure 4.3.1).

Parameter	**Hourly durations**					**Daily durations**								
	1	**2**	**3**	**6**	**12**	**1**	**2**	**4**	**7**	**10**	**20**	**30**	**45**	**60**

4.4. AMS screening and quality control

4.4.1. Record length

In NOAA Atlas 14, record length is characterized by the number of years for which annual maxima could be extracted (and is termed data years) rather than the entire period of record. In this project, only daily stations with 20 or more data years and hourly stations with 15 or more data years were used in the precipitation frequency analysis. Record lengths for daily stations varied between 20 and 100 with an average of 44 data years and a median of 38 data years (Table 4.4.1). Three additional daily stations (supplemental stations) with less than 20 years of data were retained in the dataset to assist in spatial interpolation process (see Section 4.6). The record lengths of the hourly stations varied between 15 and 43, with 32 data years on average and a median of 35 data years. Three of the four available n-minute records had more than 15 years of data, with an average of 20 data years. Figure 4.4.1 shows the number of stations within given ranges of data years for 1-day and 1-hour durations. The number of stations and the number of data years for longer daily durations may vary due to accumulated data. The records for all durations extended through December 2005.

Table 4.4.1. Record length statistics for daily, hourly, and n-minute stations used in the analysis.

Duration	**Number of stations**	**Record length (data years)**			
		minimum	**average**	**median**	**maximum**
1-day	337	20	44	38	100
1-hour	71	15	32	35	43
n-minute	3	17	20	18	25

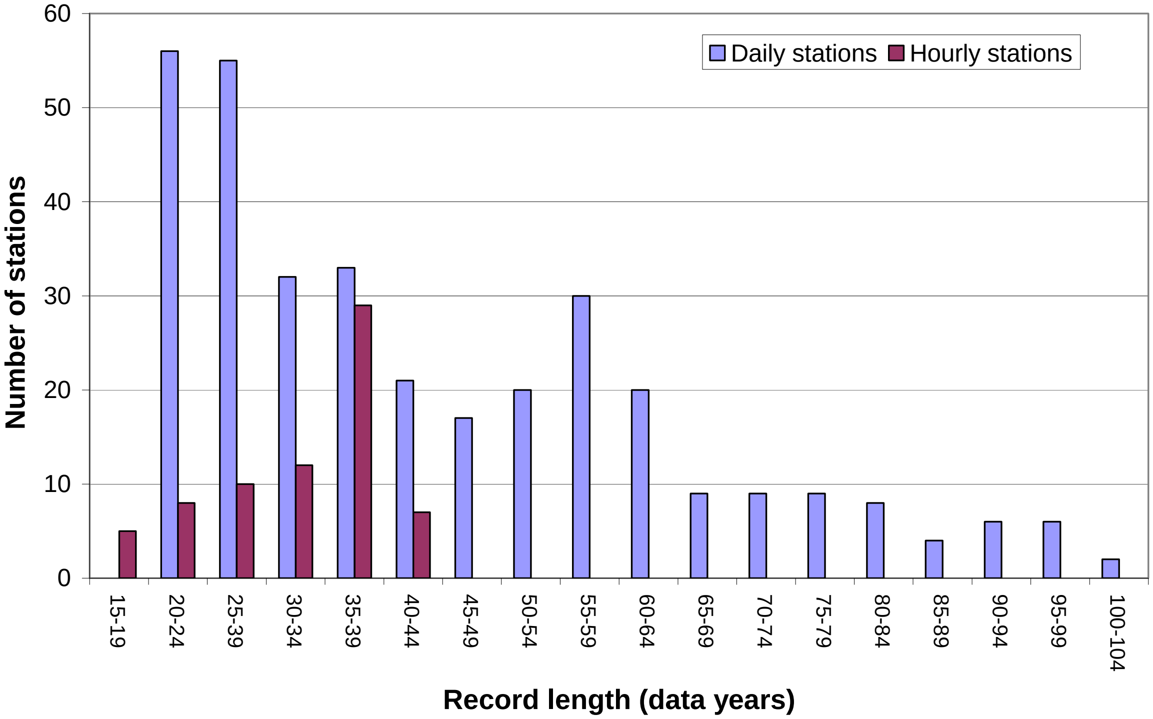

Figure 4.4.1. Number of daily and hourly stations used for precipitation frequency analysis grouped by record length.

4.4.2. Outliers

For this project, outliers are defined as annual maxima which depart significantly from the trend of the remaining maxima at a given station for a given duration. Since data at both high and low extremities can considerably affect precipitation frequency estimates, they have to be carefully investigated and either corrected or removed from the AMS if due to measurement errors. The Grubbs-Beck statistical test for outliers (Interagency Advisory Committee on Water Data, 1982) and the median +/- two standard deviations thresholds were used to identify low and high outliers for all durations.

Examination of low outliers indicated that almost all of them were from years with a significant percent of missing and/or accumulated data. They were presumed untrue maxima and were removed from the datasets. All values identified as high outliers were mapped with concurrent measurements taken at nearby stations. Values that were recommended for further investigation were then checked against original records, climatological bulletins, and/or local expertise at the National Weather Service Forecast Office in Hawaii. Depending on the outcomes of investigation, values were kept in the dataset, corrected and kept, or removed from the datasets.

4.4.3. Inconsistencies across durations

Annual maxima were compared across durations for each year. If station data had a significant number of missing and/or accumulated data, cases could exist where extracted shorter duration annual maxima were greater than corresponding longer duration annual maxima. In those cases, shorter duration precipitation amounts were used to replace annual maxima extracted for longer durations.

Co-located stations. Co-located stations are defined as stations that have the same metadata (primarily geospatial data but may also have the same identification numbers as in the case of NCDC stations), but report data at different time intervals. 1-hour AMS at co-located hourly and 15-minute stations were compared for overlapping periods of record. Similarly, 1-day AMS at co-located daily, hourly and 15-minute stations were compared for overlapping periods of record. Where corresponding AMS were significantly different, efforts were made to identify source of error and to correct erroneous observations across all durations that may be affected.

4.4.4. AMS correction factors for constrained observations

Daily durations. The majority of daily AMS data used in this study came from daily stations at which readings were taken once every day at fixed times (constrained observations). Due to the fixed beginning and ending of observation times at daily stations, it is likely that extracted (constrained) annual maxima were lower than the true (unconstrained) maxima. To account for the likely failure of capturing the true-interval 24-hour maxima, correction factors were applied to constrained AMS extracted from data recorded at daily stations. Slope coefficients of zero-intercept regression models of concurrent (occurring within +/- 1 day) unconstrained and constrained annual maxima for a given duration at co-located stations were used to estimate correction factors. Correction factors for all daily durations are given in Table 4.4.2. As can be seen from the table, the effects of constrained observations were negligible for durations of 4 days or more.

Table 4.4.2. Correction factors applied to constrained daily AMS data.

Duration (days)	Correction factor
1	1.10
2	1.07
4 or more	1.00

Hourly durations. Similar adjustment was needed on hourly AMS data extracted from hourly stations to account for the effects of constrained ‘clock hour' to unconstrained 60-minute observations. Because there were only 4 co-located hourly and n-minute stations, the conversion factors were estimated using concurrent unconstrained and constrained monthly maxima for a given hourly duration. Correction factors applied to AMS from hourly data are given in Table 4.4.3. Correction factors for durations of 3 hours or longer were estimated to be 1.0.

Table 4.4.3. Correction factors applied to constrained hourly AMS data.

Duration (hours)	Correction factor
1	1.11
2	1.06
3 or more	1.00

N-minute durations. No correction factors were applied to n-minute durations.

4.4.5. AMS trend analysis

Precipitation frequency analysis methods used in NOAA Atlas 14 volumes are based on the assumption of a stationary climate over the period of observation (and application). Statistical tests for trends in AMS and the main findings for this project area are described in more detail in Appendix A.2. Briefly, the stationarity assumption was tested by applying a parametric *t*-test and non-parametric Mann-Kendal test for trends in the annual maximum series data at 5% significance level.

Statistical tests were done on the 1-day and 1-hour AMS. Both tests identified trends in about 20% of the 1-day AMS data and no trends in 1-hour AMS. There were more negative than positive trends in the 1-day AMS. The relative magnitude of any trend in AMS for project area as a whole was also assessed by linear regression techniques. AMS were rescaled by corresponding mean values and then regressed against time. The regression results were tested as a set against a null hypothesis of zero serial correlation (zero regression slopes). The null hypothesis of no trends in AMS data could not be rejected at 5% significance level. Because all tests basically indicated no (positive) trends in the data, the assumption of stationary climate was accepted for this project area and no adjustment on AMS was recommended.

4.5. Precipitation frequency estimates with confidence intervals at stations

4.5.1. Overview of methodology and related terminology

Precipitation magnitude-frequency relationships at individual stations have been computed using an index-flood regional frequency analysis approach based on L-moment statistics, as outlined by Hosking and Wallis (1997). Frequency analyses were carried out on annual maximum series (AMS) for the following n-minute durations: 5-minute, 10-minute, 15-minute, and 30-minute, for the following hourly durations: 1-hour, 2-hour, 3-hour, 6-hour, and 12-hour, and for the following daily durations: 1-day, 2-day, 4-day, 7-day, 10-day, 20-day, 30-day, 45-day and 60-day. AMS-based precipitation frequency estimates were converted to partial duration series (PDS) based frequency estimates using Langbein's formula that allows for conversion between AMS and PDS frequencies. To allow for assessment of uncertainty in estimates, 90% confidence intervals were constructed on AMS and PDS frequency curves using a simulation-based procedure described in Hosking and Wallis (1997).

Frequency analysis involves mathematically fitting an assumed distribution function to the data. Distribution functions commonly used to fit precipitation data include 3-parameter distributions such as Generalized Extreme Value (GEV), Generalized Normal (GNO), Generalized Pareto (GPA), Generalized Logistic (GLO) and Pearson Type III (PE3), the 4-parameter Kappa (KAP) distribution, and the 5-parameter Wakeby (WAK) distribution. When fitting a distribution to a precipitation annual maximum series extracted at a given location (and selected duration), the result is a frequency distribution relating precipitation magnitude to its annual exceedance probability (AEP). The inverse of the AEP is frequently referred to as the average recurrence interval (ARI), also known as return period. When used with the AMS-based frequency analysis, ARI does not represent the "true" average period between exceedances of a given precipitation magnitude, but the average period between years in which a given precipitation magnitude is exceeded at least once. Those two average periods can be considerably different for more frequent events. The "true" average recurrence interval (ARI) between cases of a particular magnitude can be obtained through frequency analysis of PDS.

Differences in magnitudes of corresponding frequency estimates (i.e., quantiles) from the two series are negligible for ARIs greater than about 15 years, but notable at smaller ARIs (especially for ARI ≤ 5 years). Because the PDS can include more than one event in any particular year, the results from a PDS analysis are generally considered to be more reliable for designs based on frequent events (e.g., Laurenson, 1987). To avoid confusion, we use the term AEP with AMS frequency analysis and ARI with PDS frequency analysis. The term 'frequency' is interchangeably used to specify the ARI and AEP.

L-moments provide an alternative way of describing frequency distributions to traditional product moments (conventional moments) or maximum likelihood approach. They are well suited for analysis of precipitation data that exhibit significant skewness. Because sample estimators of L-moments are linear combinations of ranked observations, they are less subject to bias in estimation and are less susceptible to the presence of outliers in the data than conventional moments. Furthermore, it has been shown that L-moment estimators of GEV distribution parameters (which is the distribution found to be most representative in this project; see Section 4.5.3) compare favorably with parameter estimators obtained from either conventional moments or maximum likelihood approach, especially for small to moderate sized samples (Hosking and Wallis, 1997). L-moments that are typically used to describe various frequency distributions include 1st and 2nd order L-moments: L-location (λ_1) and L-scale (λ_2), and the following L-moment ratios: L-CV (τ), L-skewness (τ_3), and L-kurtosis (τ_4). L-CV, which stands for "coefficient of L-variation", is calculated as the ratio of L-scale to L-location (λ_2/λ_1). L-skewness and L-kurtosis are calculated as ratios of the 3rd order (λ_3) and 4th order (λ_4) L-moments to the 2nd order (λ_2) L-moment, respectively, and are therefore independent of scale.

One of the primary problems in frequency analysis is the need to provide frequency estimates for average recurrence intervals that are significantly longer than available records. The regional approach, which uses data from all stations that form a homogeneous region to obtain quantiles at a single station, has been shown to yield more accurate estimates of extreme quantiles than other approaches that use data from only a single station. The regional approach of choice for this project is the index-flood regional frequency analysis approach. The term 'index-flood' comes from its first applications in flood frequency analysis (Dalrymple, 1960), but the method is applicable to precipitation or any other type of data. The underlying assumption of the index-flood approach is that all stations in a homogeneous region have a common magnitude-frequency curve (regional growth curve) that becomes station-specific after applying a station-specific scaling factor (index-flood).

This underlying assumption is validated by testing discordancy and heterogeneity for each region (see below). The scaling factor is typically the mean of the data at a given location. Accordingly, the mean of the annual maximum series extracted from the precipitation record for a given station and selected duration was the scaling factor in this project. Station-specific estimates of L-location and regional estimates of L-CV, L-skewness and L-kurtosis are used to calculate distribution parameters and quantiles. Regional values of L-moment ratios are obtained from station-specific L-moment ratios weighted by record lengths. They are used to calculate quantiles of a regional dimensionless distribution, called regional growth factors (RGFs), for selected AEPs. Because the distribution parameters are constant for each region, there is a single set of RGFs for each region for a specified duration. The RGFs are then multiplied by the corresponding station-specific scaling factors to produce the quantiles at each frequency and duration for each station.

A frequency curve that is calculated from sample data represents some average estimate of the population frequency curve, but there is a high probability that the true value actually lies above or below the sample estimate. Confidence limits determine values between which one would expect the true value to lie with certain confidence. The width of a confidence interval between the upper and lower confidence limits is affected by a number of factors, such as the degree of confidence, sample size, exceedance probability, distribution selection, and so on. Simulation-based procedures were used in this project to estimate confidence limits of a 90% confidence interval on frequency curves. Precipitation frequency estimates from this Atlas are point estimates, and are not directly applicable for an area. The conversion of a point to an areal estimate is usually done by applying an appropriate areal reduction factor to the average of the point estimates within the subject area. Areal reduction factors are generally a function of the size of an area and the duration of the precipitation. Since there are no areal reduction factors developed specifically for Hawaii, the depth-area-duration curves from the Technical Paper No. 43 (U.S. Weather Bureau, 1962), that are identical to curves from the Technical Paper No. 29 (U.S. Weather Bureau, 1960) developed for the contiguous United States, could be used for that purpose.

4.5.2. Delineation of homogeneous regions

Initial delineation of regions. Cluster analysis was used to initially group stations into regions. Hypothetically, regionalization could be done for each duration independently, but that could result in inconsistencies in magnitude-frequency relationships over the various durations. Given that the cluster analysis on 1-day and 10-day AMS did not show significant differences in regional boundaries, it was decided to construct a single set of regions applicable to all daily durations (daily regions). Regional groups obtained through cluster analysis were initially improved based on 1-day statistical measures, physical considerations, and climatology of extreme events. Regions were further refined based on the statistical measures obtained through analysis of longer durations.

Because there were significantly less hourly than daily stations and to avoid regions with no stations for hourly durations, regions for durations < 24 hours (hourly regions) were delineated independently. Initial hourly regions obtained through cluster analysis were refined based on 1-hour statistical measures, comparisons with daily regions, and climatology of short-term precipitation extremes. All daily and hourly regions were finalized based on consultations with local climate experts.

Initial regions were formed through cluster analysis using one of the nonhierarchical clustering methods, K-mean algorithm, because of its resistance to outliers (McQueen, 1967). Nonhierarchical clustering algorithms start with predefined clusters that can be formed randomly and then reassign the cluster membership based on the similarity between stations that is measured by the Euclidian distance in terms of the selected attribute variables (Everitt et al., 2001). The set of prospective attribute variables for daily durations included at-station values of: latitude, longitude, elevation, mean annual precipitation, mean annual maximum 24-hour precipitation, and maximum observed 24-hour precipitation. Only the latter three were used in the final clustering algorithm. Similarly, for hourly durations, the following attribute variables were selected: mean annual precipitation, mean annual maximum 1-hour precipitation, and maximum observed 1-hour precipitation. Since cluster analysis is sensitive to differences in ranges for attribute variables, all variables were transformed to make their ranges comparable before they were used in cluster analysis. After several iterations, an initial set of seven daily clusters and four hourly clusters was accepted.

Refinement of regions. The daily and hourly regions delineated by the clustering procedure were investigated for heterogeneity using discordancy and heterogeneity measures, as suggested by Hosking and Wallis (1997). For daily regions, statistical measures were first investigated using 1-day data. Similarly, for hourly regions, initial homogeneity investigation was done using 1-hour data.

Discordancy measure (D) was used to determine if a station had been inappropriately assigned to a region. The measure was calculated for each station in a region as the distance of a point in a 3-dimensional space represented by at-station estimates of three L-moment ratios (L-CV, L-skewness and L-kurtosis) from the cluster center that was defined using the unweighted average of the three L-moment ratios from all stations within the region. Stations that were flagged as discordant ($D > 3$) were first investigated for erroneous data in the AMS. However, since the data had already undergone quality checks, high discordancy values were more likely to indicate that a station was discordant with the rest of the stations in the region than the existence of errors in the data.

Heterogeneity measures (H) were used to judge the relative heterogeneity of a proposed region as a whole based on L-moment ratios. Heterogeneity measures compared the variability of sample estimates of L-moment ratios in a region relative to their expected variability. Expected variability of L-moments was obtained through simulations using the Kappa distribution as the underlying population distribution. The Kappa distribution includes several 3-parameter distributions as special cases, so its results are less affected by the choice of distribution. The heterogeneity measure, H1 that examines the variability of sample estimators of L-CV was used in this project to judge the relative heterogeneity in the proposed regions. H1 is generally accepted to be the most reliable among potential heterogeneity measures in discriminating between homogeneous and heterogeneous regions. A region is generally considered homogenous if H1 is less than 2.0.

An iterative modification of regions was conducted to reduce discordancy and heterogeneity measures. Several discordant stations were reassigned to different regions; several regions were redefined or divided into sub-regions. The daily regions delineated based on 1-day AMS were further refined by investigating heterogeneity measures for other daily durations. Similarly, the hourly regions delineated based on 1-hour AMS were further refined by investigating heterogeneity measures for other hourly durations.

In all cases where H1 was greater than 2.0, sensitivity tests showed that one or several stations were driving the H1 measure due to the nature of their data sampling. If omitting the offending station(s) decreased H1 significantly and changed the 100-year estimates and regional growth factors by 5% or less, then the high H1 values in these cases were accepted without modifying the regions themselves.

After numerous iterations, 28 daily regions and 11 hourly regions were formed. Figure 4.5.1 shows regional groupings for daily durations. Figure 4.5.2 shows regional groupings for hourly durations. Appendix A.3 and A.4 list the regionally-averaged L-moment statistics and H1 values, respectively, for all regions and durations. All 28 daily regions were homogeneous (H1 < 2.0) with respect to the 1-day duration and the majority of other daily durations. Similarly, H1 measure was less than 2.0 for nearly all hourly regions and durations.

Station dependence. One of the assumptions in the index-flood method is that annual maxima extracted at different stations inside a homogeneous region are independent. Precipitation events, especially at longer durations, typically affect an area large enough to contain more than one station. Daily AMS data were investigated in each region for cross correlation between stations to assess inter-station dependence. Stations within a region were analyzed using a *t*-test at the 90% confidence level for correlation coefficients. Cross correlation between stations in the project area was not found to be statistically significant for a majority of cases analyzed, so it was assumed that the impact of potential station dependence on the precipitation quantiles and confidence intervals is negligible.

4.5.3. AMS-based frequency estimates

Choice of distribution. The goodness-of-fit test based on L-moment statistics for 3-parameter distributions, as suggested by Hosking and Wallis (1997), was used to assess which of the commonly used 3-parameter distributions (GEV, GNO, GLO, GPA, PE3) provide acceptable fit to the AMS data. Although it is not required that the same type of distribution is used for each region and duration, choosing a different distribution for different durations (and/or regions) may lead to inconsistencies between frequency estimates across durations (and/or nearby stations). Therefore, the test results were also used to identify if there was any particular distribution that gave an acceptable fit to the AMS data across a majority of regions and durations. Among tested distributions, GEV and GNO gave an acceptable fit in most cases. For example, they provided acceptable fit in 23 of 28 daily regions for 1-day data and in 10 of 11 regions for 1-hour data. L-moment ratios for various regions and durations on L-kurtosis versus L-skewness plots tended to cluster around the GEV distribution more than any other distribution. Since the GEV distribution is a distribution typically used to describe precipitation data, the decision was made to adopt GEV distribution for all regions and for all durations.

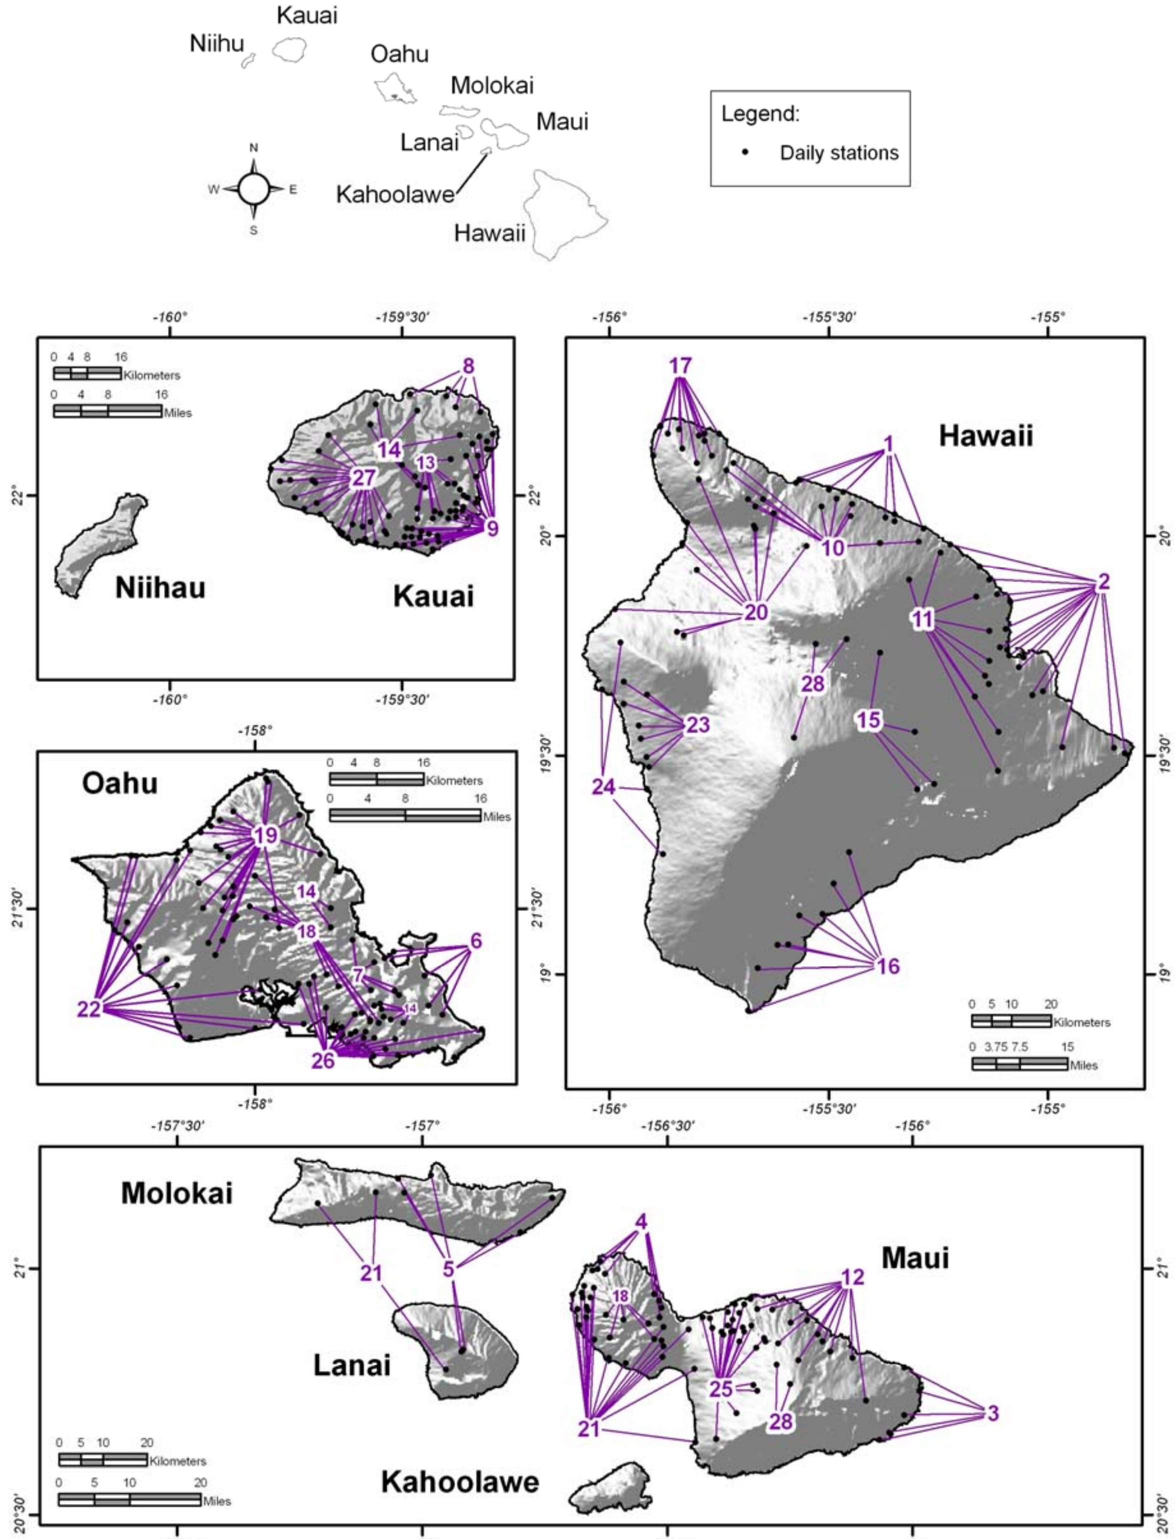

Figure 4.5.1. Station groupings for daily durations.

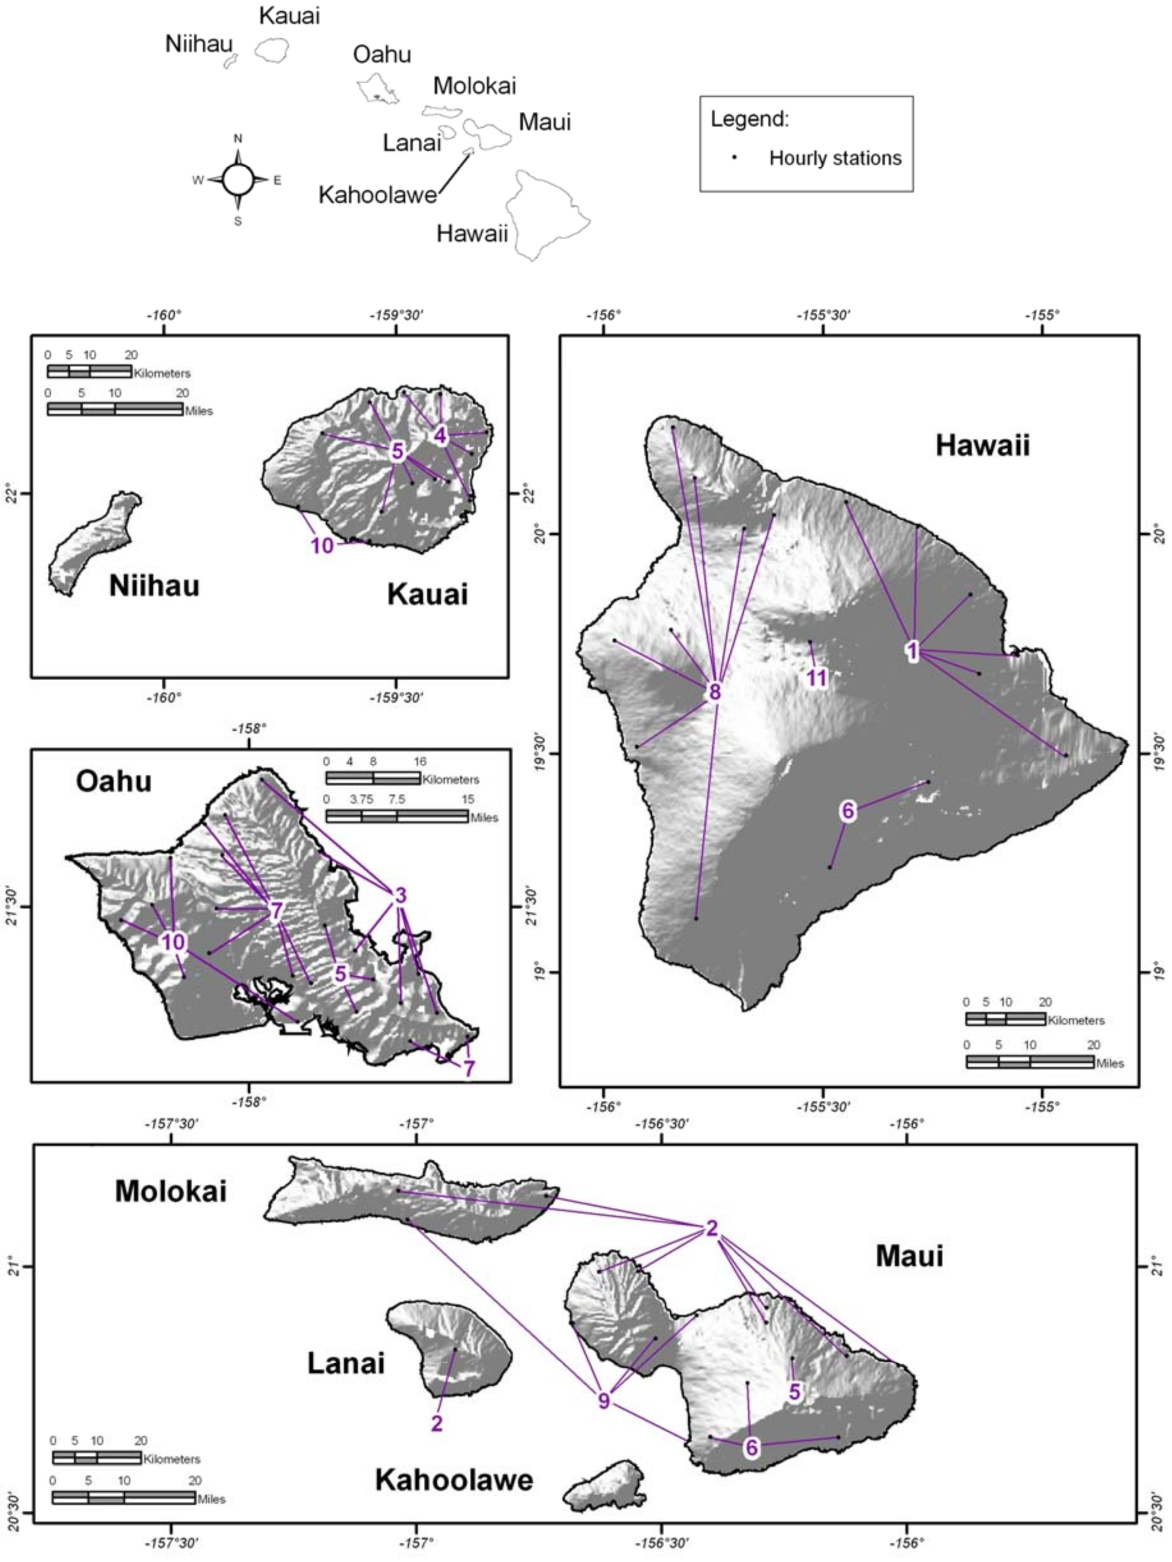

Figure 4.5.2. Station groupings for hourly durations.

Frequency estimates for daily and hourly durations. For a given daily (hourly) duration, regional estimates of L-CV, L-skewness and L-kurtosis for each of the 28 daily regions (11 hourly regions) were obtained from station specific L-moment ratios weighted by record lengths. They were used to calculate parameters of a regional dimensionless GEV distribution and to calculate regional growth factors for selected AEPs (1/2, 1/5, 1/10, 1/25, 1/50, 1/100, 1/200, 1/500 and 1/1000). The RGFs were then multiplied by station-specific mean annual maximum values to produce quantiles for each selected frequency and duration for all stations in the region. This calculation was repeated for all regions and for all durations. Appendix A.5 lists the RGFs for all regions and durations.

Frequency estimates for supplemental stations. Three stations (called supplemental) located in remote areas (see Figures 4.2.1 and 4.2.2 for their locations and Table A.1.3 in Appendix A.1 for their metadata) that did not have sufficient data to be used in frequency analysis were retained primarily to assist in spatial interpolation of mean annual maxima and precipitation frequencies (see Section 4.6). The stations were assigned to appropriate daily and hourly regions. Mean annual maxima for all durations at those three locations were estimated based on available data, spatially interpolated values, and information available from Technical Papers No. 43 and No. 51. Precipitation frequency estimates for each frequency and duration were then obtained by multiplying mean annual maxima with appropriate RGFs.

Frequency estimates for n-minute durations. Because only four n-minute stations were available in the whole project area (see Figure 4.2.2 for their locations), n-minute precipitation frequencies were estimated by applying linear scaling factors to corresponding unconstrained 1-hour (i.e., 60-minute) frequencies at hourly stations. Three n-minute stations had at least 15 years of data and were analyzed as one region. The n-minute scaling factors were calculated as the average of ratios of 5-, 10-, 15-, and 30-minute annual maxima to corresponding unconstrained 60-minute annual maxima. These scaling factors were applied to all unconstrained 1-hour quantiles to estimate quantiles at n-minute durations. Table 4.5.1 shows the n-minute scaling factors used in this project.

Table 4.5.1. Scaling factors applied to unconstrained 1-hour quantiles to estimate quantiles for n-minute durations.

Duration (minutes)	5	10	15	30
Scaling factor	0.29	0.43	0.54	0.76

Consistency in frequency estimates across durations. All precipitation quantiles were inspected for inconsistencies across durations. Since the quantiles at a given station were calculated independently for each duration, it could happen that quantile estimate for a given frequency was higher for a shorter duration than the next longer duration. The underlying causes for each of those irrational estimates were carefully inspected. The majority of anomalous cases were caused by data sampling variability across durations, particularly because record length at one duration was significantly shorter compared to record lengths at other durations. Some irregularity occurred at co-located stations because different regionalization was used for hourly and daily durations. Finally, there were a few cases caused by random variation of distribution parameterization between durations. Irrational frequency estimates were replaced with estimates that were assigned in proportion to frequency estimates at other durations that were judged reliable.

4.5.4. PDS-based frequency estimates

As mentioned in Section 4.3, partial duration series were not extracted from the precipitation datasets in this project. Instead, PDS-based quantiles were estimated indirectly using the Langbein’s formula

(Langbein, 1949) that transforms PDS-based average recurrence intervals (ARIs) to annual exceedance probabilities (AEPs):

$$\mathrm{AEP} = 1 - \exp\left(-\frac{1}{\mathrm{ARI}}\right).$$

PDS-based frequency estimates were calculated for the same durations as AMS-based estimates. For a given daily or hourly duration, PDS-based quantiles were calculated for 1-, 2-, 5-, 10-, 25-, 50-, 100-, 200-, 500- and 1,000-year ARI. Selected ARIs were first converted to AEPs using the above formula and then used to calculate regional growth factors following the same regional approach and using the same L-moments that were used in the AMS analysis (analysis was done simultaneously for both time series). The RGFs were finally rescaled by the station-specific mean annual maxima to produce the PDS-based quantiles for each station. Calculations were repeated for all selected durations between 1-hour and 60-day. N-minute estimates were obtained using the scaling factors calculated for AMS-based quantiles.

4.5.5. Confidence limits

A Monte Carlo simulation procedure, as described in Hosking and Wallis (1997), was used to construct 90% confidence intervals (i.e., 5% and 95% confidence limits) on both AMS-based and PDS-based precipitation frequency curves. For each region and for each hourly and daily duration, 1,000 simulated datasets were generated using the same number of stations and associated record lengths as in actual regions. They were used to generate 1,000 frequency estimates at each station using the same distribution that was fitted to original data. Generated frequency estimates were sorted from smallest to largest and the 50th value was selected as the lower confidence limit and the 950th value was selected as the upper confidence limit. Confidence limits for n-minute durations were calculated from unconstrained 1-hour confidence limits using the same n-minute scaling factors that were used to estimate n-minute frequency estimates.

4.6. Derivation of grids

4.6.1. Mean annual maxima

As explained in Section 4.5.1, mean annual maximum values at a station serve as scaling factors to generate station-specific precipitation frequency estimates from regional growth factors (RGFs) for both AMS and PDS data. The station mean annual maximum values for selected durations were spatially interpolated to produce mean annual maximum (index-flood) grids using a hybrid statistical-geographic approach for mapping climate data named Parameter-elevation Regressions on Independent Slopes Model (PRISM) developed by Oregon State University's PRISM Group (e.g., Daly et al., 2002). Selected durations included: 60-minute, 2-hour, 3-hour, 6-hour, 12-hour, 24-hour, 2-day, 4-day, 7-day, 10-day, 20-day, 30-day, 45-day and 60-day. The resulting high-resolution (15 x 15-seconds; that is approximately 400 x 400 meters, or 1321 x 1321 feet) mean annual maximum grids then served as the basis for deriving gridded precipitation frequency estimates at different recurrence intervals using the Cascade, Residual Add-Back (CRAB) spatial interpolation procedure (described in Section 4.6.2).

Appendix A.6 provides detailed information on the PRISM-based methodology for creating mean annual maximum grids. In summary, PRISM used mean annual precipitation grids (USDA-NRCS, 1998) to estimate mean annual maximum grids. Mean annual precipitation (actually, the square-root of mean annual precipitation) was used as the predictor because it is based on a large data set, accounts for spatial variation of climatic information and is consistent with methods used in previous projects, including NOAA Atlas 2 (Miller et al., 1973) and prior volumes of NOAA Atlas 14 (Bonnin et al., 2004a; Bonnin et al., 2004b; Bonnin et al., 2006). PRISM used a unique regression function for each target grid cell that accounted for: user knowledge, the distance of an observing station to the target cell, the difference between station's and target cell's mean annual precipitation, topographic facet, coastal proximity, etc. PRISM cross-validation statistics were computed where each observing station was deleted from the data set one at a time and a prediction made in its absence. Results indicated that for this project area, overall bias was less than 2 percent and the mean absolute error was less than 12 percent.

Because of the limited hourly (< 24-hour) data for this project, additional effort was made to bring the hourly station density up to that of the daily (≥ 24-hour) stations by objectively developing hourly mean annual maximum data for daily-only stations. Those data were used during the PRISM modeling of hourly durations (see Appendix A.6 for more detail).

4.6.2. Precipitation frequency estimates

24-hour through 60-day durations. An HDSC-developed spatial interpolation technique termed the Cascade, Residual Add-Back (CRAB) was used to convert mean annual maximum grids into grids of AMS-based and PDS-based precipitation frequency estimates for various frequencies and durations. The CRAB procedure is based on the approach used in derivation of several maps for the National Climatic Data Center's Climate Atlas of the United States (Plantico et al., 2000).

The technique derives grids along the frequency dimension with station precipitation frequency estimates for different durations being separately interpolated. Hence, the evolution of frequency-dependent spatial patterns for a given duration is independent of other durations. The CRAB process utilizes the inherently strong linear relationship that exists between mean annual maxima and precipitation frequency estimates for the 2–year average recurrence interval (ARI), as well as between precipitation frequency estimates for consecutive ARIs. Figure 4.6.1 shows an example of the relationship for the 24-hour duration between the 50-year and 100-year estimates for the Hawaiian Islands. The R^2 value here of 0.996 is very close to 1.0, which was common for all relationships. Since this equation was calculated using all stations in the project area, the slope coefficient of 1.132 can be thought of as an average domain-wide ratio between 100-year and 50-year quantiles for 24-hour duration.

For each duration, the cascade began with the PRISM-derived mean annual maximum (MAM) grid as the initial predictor grid and the 2-year precipitation frequency estimates as the subsequent grid. For a given duration, a single linear regression relationship was developed for mean annual maxima (predictor) and 2-year precipitation frequency estimates (predictant) from all stations in the project area. As a result of spatial smoothing during PRISM interpolation, it was possible that at-station MAM values calculated directly from AMS data were slightly different than corresponding PRISM-derived grid cell MAM estimates. To account for that difference, the PRISM MAMs were extracted for each station location and used in the computation of precipitation frequency estimates. The global linear regression relationship was applied to the MAM grid to establish the initial grid for 2-year estimates.

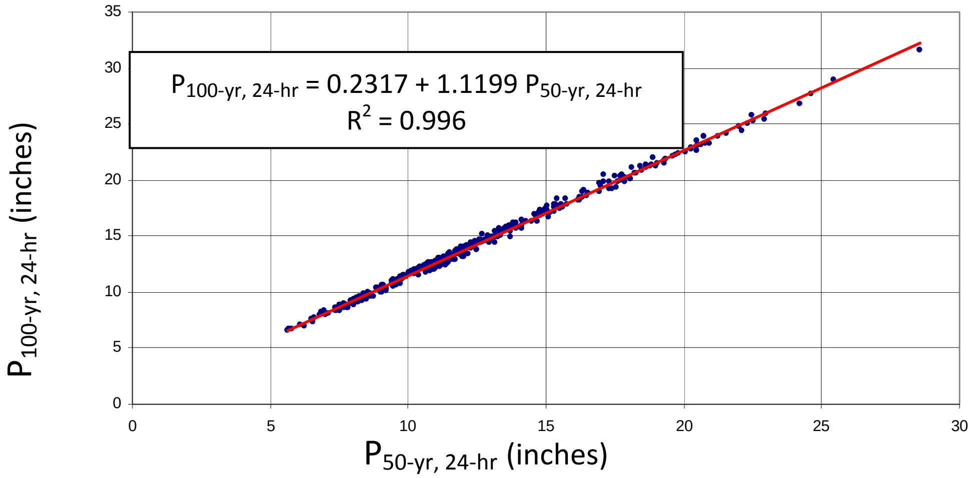

Figure 4.6.1. Scatter plot of 100-year versus 50-year precipitation frequency estimates based on 24-hour annual maximum series. Linear regression line is also shown.

Residuals were then computed for each station to quantify the difference between at-station estimates and initial gridded estimates. The residuals were normalized by the mean annual maxima and spatially interpolated to a grid using an inverse-distance-weighting (IDW) algorithm. The IDW method used in CRAB estimated the values at ungauged locations based on information from the nine closest stations. Weights were inversely proportional to the power of the distance in miles. The IDW interpolation method was selected because by definition it is an exact interpolator and therefore remains faithful to the normalized residuals at stations. Also, normalized residuals were highly correlated, so a distance-weighting type of interpolation method was appropriate. The normalized residual grid was then multiplied by the original spatially interpolated mean annual maximum grid to obtain a spatially interpolated grid of actual residuals for the entire project area. The spatially interpolated grid of actual residuals was added back to the initial grid of 2-year estimates to create a grid of 2-year precipitation frequency estimates.

In the subsequent run, 2-year precipitation frequency estimates from all stations in the project area became the predictor grid and 5-year estimates became the variable to be predicted, and so forth. 2-year precipitation frequency estimates also served as predictors for 1-year estimates.

To ensure consistency in grid cell values across all durations and frequencies, duration-based and frequency-based internal consistency checks were conducted. Frequency-based internal consistency violations (e.g., 100-year estimate < 50-year estimate) were rare and negligible relative to the precipitation frequency estimates involved. Duration-based internal consistency violations (e.g., 2-day estimate < 24-hour estimate) were more common. For inconsistent cases, the longer duration or rarer frequency grid cell value was adjusted by multiplying the shorter duration or lower frequency grid cell value by 1.01 to provide a 1% difference between the values. One percent was chosen over a fixed factor to allow the difference to change according to the grid cell magnitudes while at the same time providing a minimal, but sufficient, adjustment without changing otherwise compliant data in the process. Grid cell consistency was ensured first across durations and then across frequencies.

60-minute to 12-hour durations. The limited hourly (< 24-hour) duration dataset was not sufficient to accurately resolve patterns at the final high spatial resolution (15-seconds), therefore so called hourly “pseudo data” were generated at all daily-only stations to create a more coherent spatial pattern in the hourly durations. This increased the hourly duration dataset by 292 stations (from 71 to 363 stations), thereby providing the station density necessary to accurately resolve important spatial patterns that would have otherwise been undetected. Adding such data reduces uncertainty in areas with no hourly data.

The pseudo precipitation frequency estimates were generated by applying ratios of x-hour estimates to 24-hour estimates that were spatially interpolated using IDW algorithm, based on co-located daily and hourly stations. The ratio at each co-located station was calculated using the hourly station's 24-hour precipitation frequency estimate to its x-hour precipitation frequency estimate. The interpolated ratio was then applied to the daily-only 24-hour precipitation frequency estimates to generate the pseudo hourly data at that station location. The mitigation provided a smoother, more meteorologically-sound transition from hourly to daily precipitation frequency estimates when the CRAB procedure was applied.

Sub-hourly (or n-minute) durations. Because of the small number of n-minute data available for the Hawaiian Islands, precipitation frequency estimates for durations shorter than 60-minute (i.e., n-minute precipitation frequency estimates) were calculated by applying n-minute scaling factors to final grids of spatially interpolated 60-minute precipitation frequency estimates. The scaling factors were developed using ratios of n-minute quantiles to 60-minute (i.e., unconstrained 1-hour) quantiles from co-located n-minute and hourly stations (see Table 4.5.1 and discussion in Section 4.5.3) and were applied for all annual exceedance probabilities and average recurrence intervals. The appropriate 60-minute grids were multiplied by the scaling factors to create the final n-minute precipitation frequency grids.

Cross-validation. Jack-knife cross-validation technique (Shao and Tu, 1995) was used to evaluate CRAB performance for interpolating precipitation frequency estimates. It was cost prohibitive to re-create the PRISM mean annual maximum grids for each cross-validation iteration. For this reason, the cross-validation results reflect the accuracy of the CRAB procedure based on the same mean annual maximum grids. Figure 4.6.2 shows validation results for 100-year, 60-minute estimates as a histogram representing the distribution of differences in 100-year 60-minute estimates with and without each station. For approximately 75% of stations in the project area, differences were less than ±5%. The largest differences were up ±15%, but they occurred in less than 7% of all stations. Based on the results shown in the figure, overall CRAB did a good job in reproducing the values in the absence of station data. There is a tendency for CRAB to slightly under-predict the precipitation frequency values.

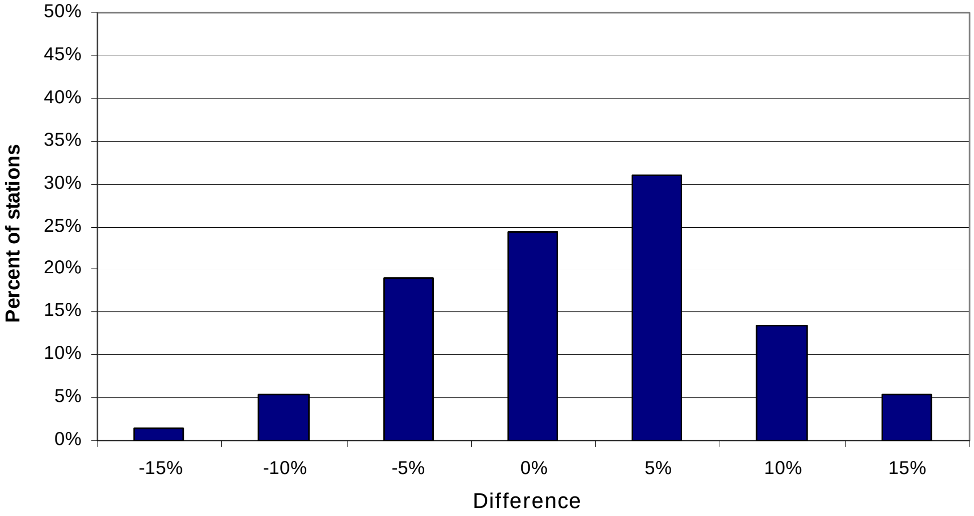

Figure 4.6.2. Jackknife cross-validation results for 100-year 60-minute estimates.

4.6.3. Confidence limits

Grids of upper and lower limits of the 90% confidence interval for the precipitation frequency estimates were also derived in the same manner as precipitation frequency grids. For 60-minute to 60-day durations, they were derived using the CRAB procedure. Similar to the precipitation frequency estimates, upper and lower limits exhibited strong linear relationships at consecutive average recurrence intervals. The PRISM-produced mean annual maximum grid for a given duration was used as the predictor for the 2-year upper (lower) limit grids. The global linear regression relationship was applied to the MAM grid to establish the initial grid for 2-year upper (lower) limit estimates. At-station residuals were spatially interpolated and used to develop the upper (lower) limit grids. In the subsequent run, 2-year upper (lower) limit estimates from all stations in the project area become predictor for 5-year upper (lower) limit estimates, and so forth. Like the precipitation frequency grids, frequency-based and duration-based adjustments were made when needed for consistency. For sub-hourly durations, grids for upper (lower) limits were then developed by multiplying 60-minute upper (lower) grids by scaling factors from Table 4.5.1.

5. Precipitation Frequency Data Server

NOAA Atlas 14 precipitation frequency estimates are delivered entirely in digital form in order to make the estimates more widely available and to provide them in various formats. The Precipitation Frequency Data Server - PFDS (http://hdsc.nws.noaa.gov/hdsc/pfds/) provides a point-and-click web portal for precipitation frequency estimates and associated information.

In early 2011 a major redesign of the PFDS web interface was done to make PFDS pages interactive. Since then, PFDS pages were enhanced on several occasions to improve the usability and readability of PFDS website's content, to increase data download speeds and to provide additional information. In order to keep this section of the documentation up-to-date for all volumes, the PFDS section is offered as a separate document. This document is updated as needed and is available for download from here: https://www.weather.gov/media/owp/hdsc_documents/NA14_Sec5_PFDS.pdf.

6. Peer review

A peer review of the Hawaiian Islands precipitation frequency project's preliminary results was carried out during the six week period starting on September 22, 2008. 115 users, project sponsors and other interested parties were contacted via email for the review. Potential reviewers were asked to evaluate the reasonableness of point precipitation frequency estimates as well as their spatial patterns. The review included the following items:

a. At- station depth-duration-frequency curves built from annual maximum series data for a range of durations for which data were available;
b. Isohyethal maps of mean annual maximum precipitation amounts for 60-minute, 12-hour, 24-hour, and 10-day durations;
c. Isohyethal maps of precipitation frequency estimates for 1/2 and 1/100 annual exceedance probabilities and 60-minute, 12-hour, 24-hour, and 10-day durations;
d. Maps showing regional groupings of stations used in frequency analysis.

The reviews provided critical feedback that HDSC used to create a better product. Reviewers' comments regarding expected spatial patterns generated further verification and/or modification of various regions and prompted development of supplemental stations in remote areas to anchor interpolation. Detailed reviewers' comments and HDSC responses can be found in Appendix A.7.

7. Comparison with previous NOAA publications

The precipitation frequency estimates in NOAA Atlas 14 Volume 4 supersede the estimates for the Hawaiian Islands previously published in the following publications:

a. *Technical Paper No. 43, Rainfall-Frequency Atlas of the Hawaiian Islands for Areas to 200 Square Miles, Durations to 24 Hours, and Return Periods from 1 to 100 Years* (U.S. Weather Bureau, 1962)

b. *Technical Paper No. 51, Two- to Ten-Day Rainfall for Return Periods of 2 to 100 Years in the Hawaiian Islands* (U.S. Weather Bureau, 1965).

Technical Paper No. 43, herein after referred to simply as TP 43, published in 1962, was the most recent update of the precipitation frequencies for the Hawaiian Islands for 5-minute through 24-hour durations. Technical Paper No. 51 (TP 51), published in 1965, provided the latest update of the precipitation frequencies for the Hawaiian Islands for 2-day to 10-day durations.

Updated precipitation frequency estimates from this Atlas were examined in relation to TP 43 and TP 51 estimates for the 100-year average recurrence interval. Investigation of spatial maps of relative differences (in percent) between NOAA Atlas 14 and TP 43 estimates for 1-day duration (Figure 7.1) and 1-hour duration (Figure 7.2) revealed that 100-year estimates for both durations changed up to ±50%, but mostly within ±15%. Areas with significant changes in precipitation frequency have been carefully investigated. They are considered reasonable and are primarily attributed to more stations and extended data sets available for this project, and also to more robust regional frequency approaches and improved spatial interpolation techniques used in this Atlas.

The disparity in available data for NOAA Atlas 14 and TP 42 is considerable, in terms of number of stations available for frequency analysis and particularly in terms of record lengths. For example, a total of 352 daily stations (the exact number available for each duration analyzed varies due to accumulated data; see Section 4.3) with record lengths ranging from 20 to 100 years (44 data years on average) were available for this project. In contrast, only 287 daily stations with periods of record between 5 and 59 years (with possibly some years with no observations) were used in some fashion in TP 43, and of those only 159 had at least 20 years of data and so could be used directly in frequency analysis. For some stations used in both projects, 41 more years of data were available for NOAA Atlas 14. Record lengths for daily stations used in each publication are shown in Figure 7.3.

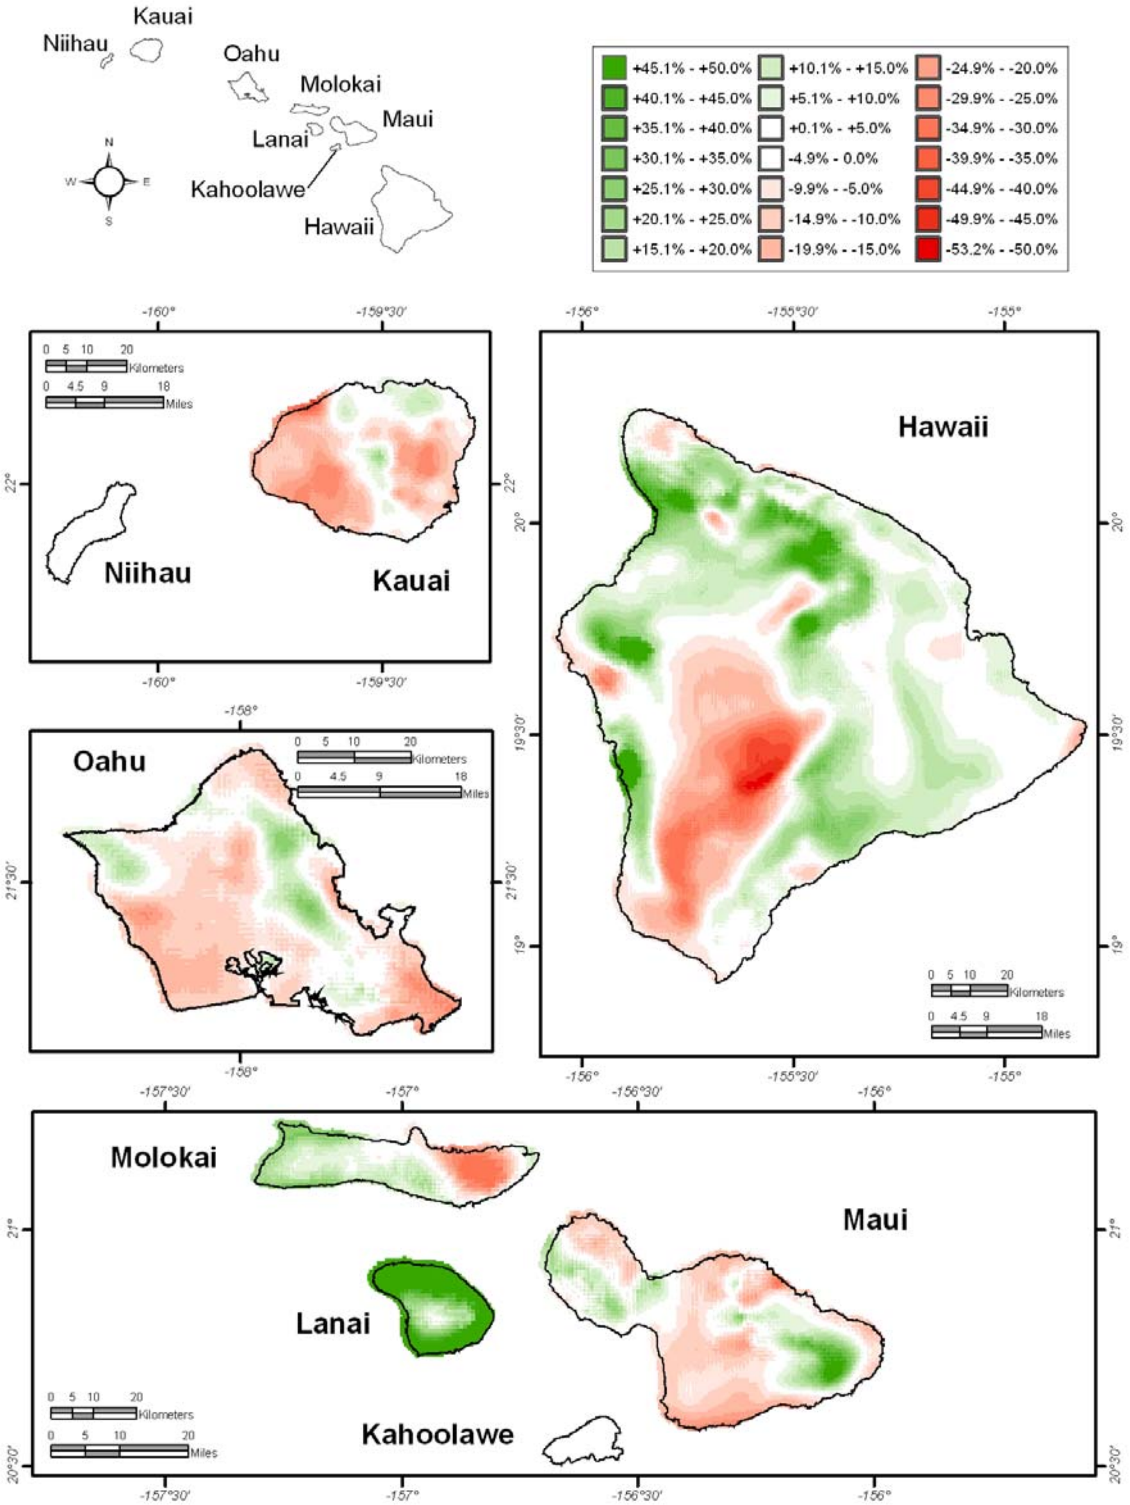

Figure 7.1. Relative differences (in percent) between NOAA Atlas 14 Volume 4 and Technical Paper 43 100-year 24-hour estimates.

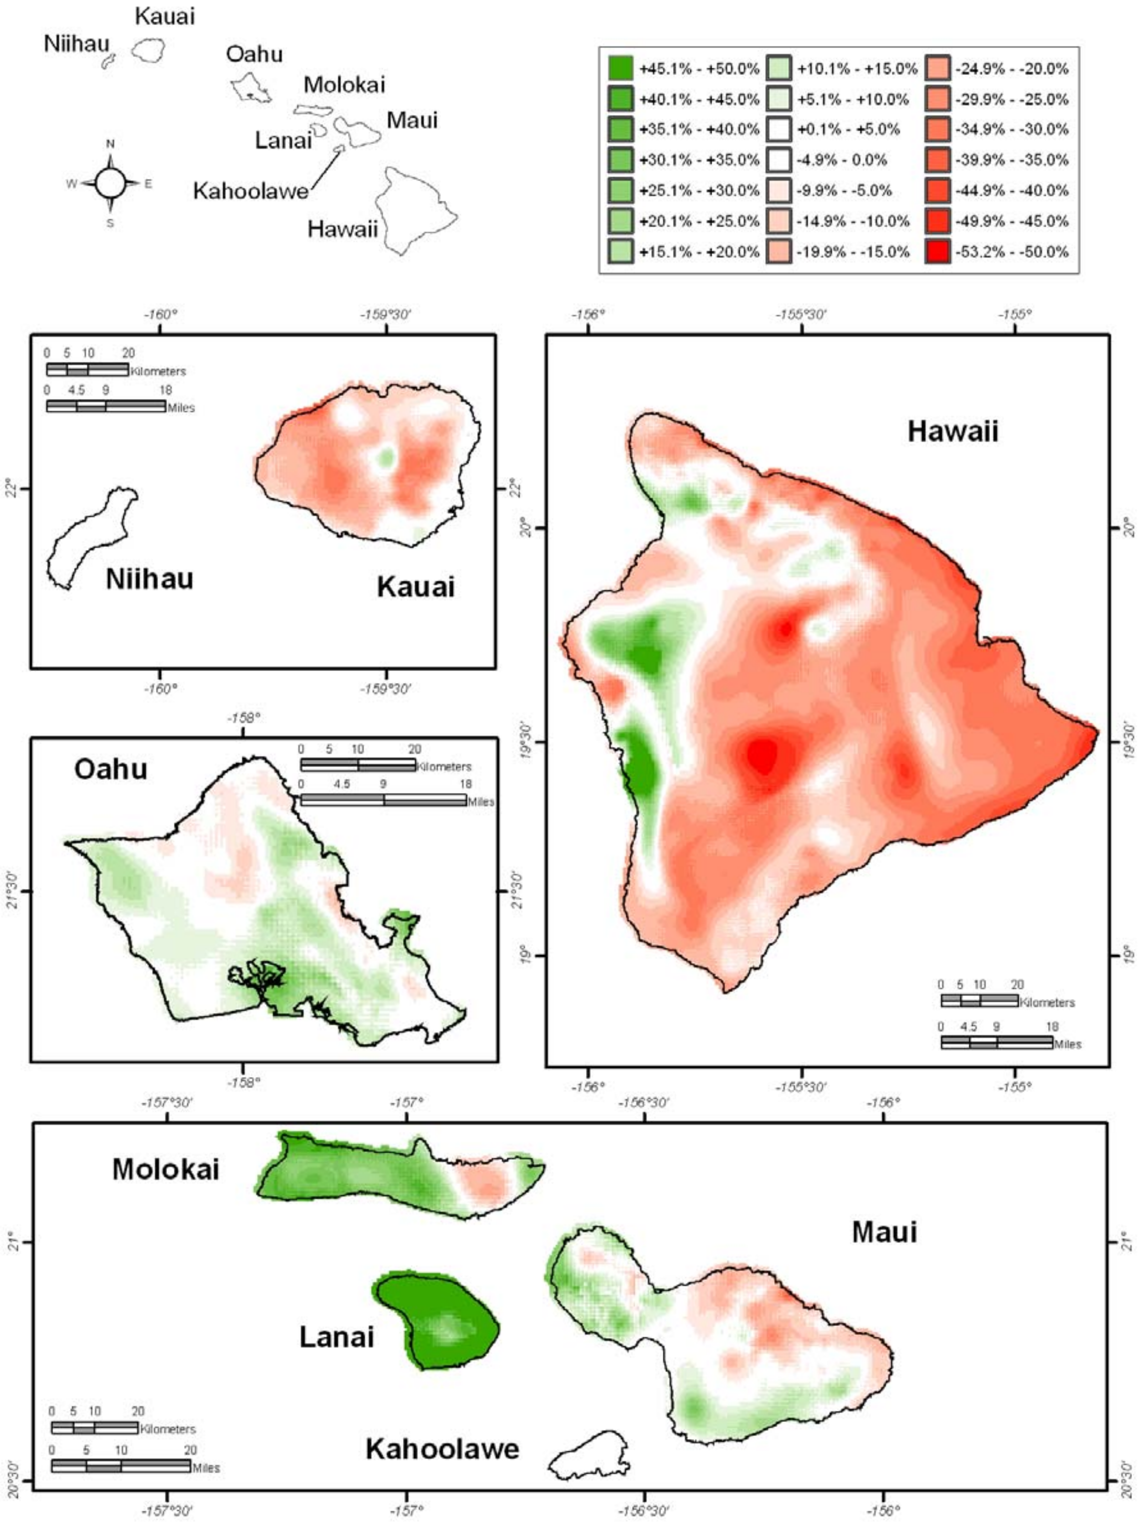

Figure 7.2. Relative differences (in percent) between NOAA Atlas 14 Volume 4 and Technical Paper 43 100-year 60-minute estimates.

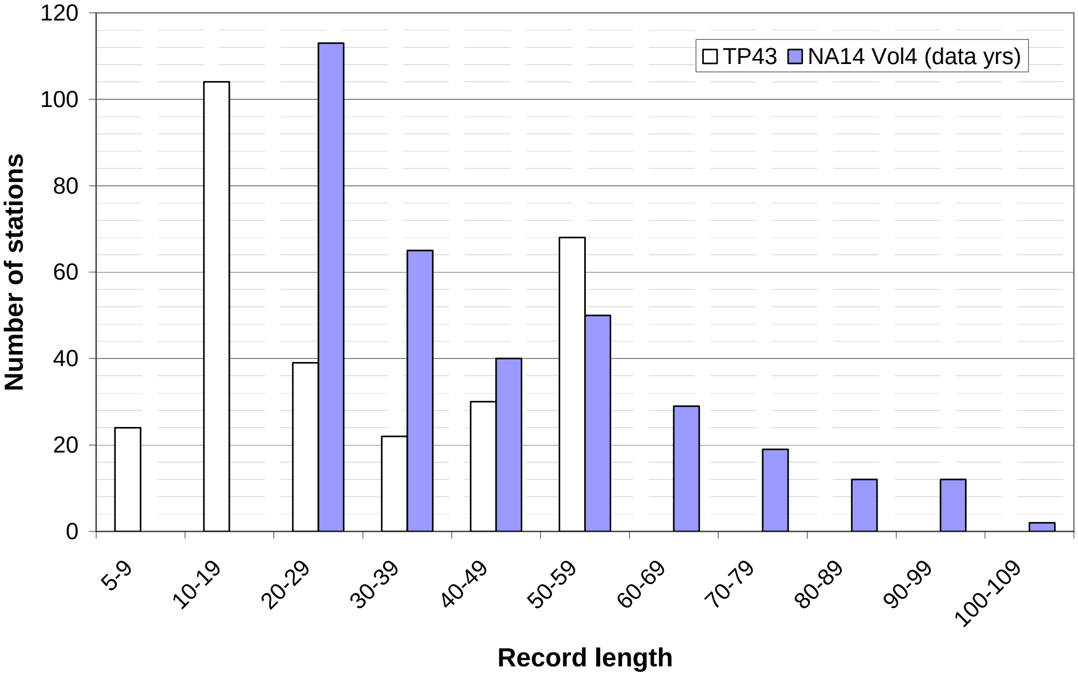

Figure 7.3. Comparison of record lengths at daily stations used in Technical Paper 43 (as years of record) and in NOAA Atlas 14 (as data years).

For longer daily durations, frequency analysis in TP 51 was done using only 52 stations with 43 years of record on average; an additional 139 stations with at least 10 years of data were used indirectly to develop relationships between 1-day and 10-day frequency estimates. In comparison, 217 to 253 daily stations (number depends on duration) were used in the NOAA Atlas 14 frequency analysis. For some stations used in both projects, 44 additional years of data were available for NOAA Atlas 14.

For hourly stations, the difference in available data between two projects is striking; 71 hourly stations were available for this project and only three hourly stations were available for TP 43, two of which had records of less than 10 years.

Evidently, the frequency analysis approach in TP 43 had to be designed to accommodate the significant percentage of stations with fairly short records; and in case of hourly durations it was based on 1-hour statistics from the continental United States. Also, isohyetal maps in TP 43 and TP 51 resulted from interpolation of frequency estimates at very few stations. This surely impacted the accuracy of the results.

Other contributors to differences in estimates are improved frequency approaches and spatial interpolation techniques used in the Atlas. In TP 43, precipitation magnitude - frequency relationships at individual stations have been computed using a single-station frequency analysis approach based on conventional moments; in NOAA Atlas 14, they were computed using an index-flood regional frequency analysis approach based on the L-moments. L-moments are generally accepted to be better suited for analysis of precipitation data that exhibit significant skewness than conventional moments; they are less subject to bias in estimation and are less susceptible to the presence of outliers in the data. The regional frequency analysis approach used in NOAA Atlas 14 has also been shown to yield more accurate estimates of extreme quantiles than the single-station frequency analysis approach used in TP 43 and TP 51.

Finally, precipitation frequency estimates are available for a wider range of durations and frequencies in NOAA Atlas 14 than in previous publications. In NOAA Atlas 14, frequency estimates are available for average recurrence intervals of up to 1,000 years and durations up to 60 days; in TP 43 and TP 51 they were available for frequencies up to 100 years and durations up to 10 days. Another important difference is that in NOAA Atlas 14, confidence intervals were constructed on AMS and PDS frequency estimates to allow for assessment of uncertainty in estimates; such information was not available from TP 43 and TP 51.

Acknowledgments

This work was funded by NOAA's National Weather Service, Office of Hydrologic Development and the U.S. Army Corps of Engineers.

We acknowledge the colleagues who provided additional data for this project beyond what was available from NOAA's National Climatic Data Center, including: Thomas Giambelluca and Mike Nullet from the University of Hawaii at Manoa; Pao-Shin Chu and Cheri Loughran from the Hawaii State Climate Office and the University of Hawaii at Manoa who digitized and provided data; and Gordon Tribble and Delwyn Oki from the U.S. Geological Survey (USGS) Pacific Islands Water Science Center.

Lastly, we acknowledge colleagues who provided comments to improve the final product, including: John Dawley of the Dam Safety Program Engineering Division in the Hawaii Department of Land and Natural Resources; William Merkel of United States Department of Agriculture's Natural Resources Conservation Service; and Delwyn Oki of the USGS Pacific Islands Water Science Center Office. Most notably, we'd like to acknowledge Kevin Kodama of NOAA/NWS Honolulu Forecast Office and Pao-Shin Chu, Hawaii State Climatologist for their collaborative effort in ensuring the quality of the input data and the final estimates.

Appendix A.1 List of stations used to prepare precipitation frequency estimates

Table A.1.1. List of daily stations used in the analysis showing island, station name, station ID, source of data, latitude, longitude, elevation, period of record and daily precipitation frequency region number (used to group stations for frequency analysis).

Appendix A.2 Annual maximum series trend analysis

1. Selection of statistical tests for detection of trends in AMS

Precipitation frequency analysis methods used in NOAA Atlas 14 volumes are based on the assumption of stationary climate over the period of observation (and application). To meet the stationarity criterion, the annual maximum series data must be free from trends during the observation period. A number of parametric and non-parametric statistical tests are available for the detection and/or quantification of trends. Selection of an appropriate statistical test requires consideration of the data tested and the limitations of the test.

Annual maximum series (AMS) were first graphed for each station in the project area to examine the time series and to observe general types of trends in the data. Visual inspection of time series plots indicated that there were no abrupt changes or apparent cycles in the AMS, but suggested the possibility of trends at some locations. Changes appeared to be gradual and approximately linear, and both increasing and decreasing trends were observed.

The null hypothesis that there are no trends in annual maximum series was tested on 1-hour and 1-day AMS data. The hypothesis was tested at each station separately and for the region as a whole at the level of significance $\alpha = 5\%$. At-station trends were inspected using the parametric t-test for trend and non-parametric Mann-Kendall test (Maidment, 1993). Both tests are extensively used in environmental science and are appropriate for records that have undergone a gradual change. The tests are fairly robust, readily available, and easy to use and interpret. Since each test is based on different assumptions and different test statistics, the rationale was that if both tests have similar outcomes there can be more confidence about the results. If the outcomes were different, it would provide an opportunity to investigate reasons for discrepancies.

Parametric tests in general have been shown to be more powerful than non-parametric tests when the data are approximately normally distributed and when the assumption of homoscedasticity (homogeneous variance) holds (Hirsch et al., 1991), but are less reliable when those assumptions do not hold. The parametric *t*-test for trend detection is based on linear regression, and therefore checks only for a linear trend in data. However, requiring a linear trend assumption seemed sufficient, since, as mentioned above, time series plots indicated monotonic changes in AMS. The Pearson correlation coefficient (r) was used as a measure of linear association for the *t*-test. The hypothesis that the data are not dependent on time (and also that they are independent and normally distributed numbers) was tested using the test statistic t that follows Student's distribution and is defined as:

$$t = \frac{r\sqrt{n-2}}{\sqrt{1-r^2}}$$

where n is the record length of the AMS. The hypothesis is rejected when the absolute value of the computed t value is greater than the critical value obtained from Student's distribution with (n-2) degrees of freedom and exceedance probability of $\alpha/2\%$, where α is the significance level. The sign of the t statistic defines the direction of the trend, positive or negative.

Non-parametric tests have advantages over parametric tests since they make no assumption of probability distribution and are performed without specifying whether trend is linear or nonlinear. They are also more resilient to outliers in data because they do not operate on data directly. One of the disadvantages of non-parametric tests is that they do not account for the magnitude of the data. The Mann-Kendall test was selected among various non-parametric tests because it can accommodate missing values in a time series, which was a common occurrence in the AMS data. The Mann-Kendall test compares the relative magnitudes of annual maximum data. If annual maximum values are indexed based on time, and x_i is the annual maximum value that corresponds to year t_i, then the Mann-Kendall statistic is given by:

$$S = \sum_{k=1}^{n-1} \sum_{i=k+1}^{n} sign(x_i - x_k).$$

The test statistic Z is then computed using a normal approximation and standardizing the statistic S. The null hypothesis that there is no trend in the data is rejected at significance level α if the computed Z value is greater, in absolute terms, than the critical value obtained from standard normal distribution that has probability of exceedance of α/2%. The sign of the statistic defines the direction of the trend, positive or negative.

In addition to at-station trend analysis, the relative magnitude of any trend in AMS for a region as a whole was assessed by linear regression techniques. Station-specific AMS were rescaled by corresponding mean annual maximum values and then were regressed against time, where time was defined as year of occurrence minus 1900. The regression results from all stations were tested against a null hypothesis of zero serial correlation (zero regression slopes).

2. Trend analysis and conclusions

The null hypothesis that there are no trends in annual maximum series was tested on 1-day and 1-hour AMS data at each station in the project area with at least 30 years of data. 274 daily stations and 53 hourly stations satisfied the record length criterion. The *t*-test and Mann-Kendall (MK) test for trends were applied to test the hypothesis. As can be seen from Table A.2.1, results from both tests were essentially the same for both 1-day and 1-hour AMS. For the 1-day duration, tests indicated no statistically-significant trends in approximately 80% of stations tested. In the 20% of stations where trends were detected, almost all of them were negative. For the 1-hour duration, the *t*-test detected a negative trend at one location; otherwise, no statistically-significant trends were detected by either test. Spatial distribution of trend analysis results for 1-day AMS and 1-hour AMS is shown in Figures A.2.1 and A.2.2., respectively.

Table A.2.1. Trend analysis results based on *t*-test and Mann-Kendall (MK) test for 1-day and 1-hour AMS data.

	1-day AMS		**1-hour AMS**	
	***t*-test**	**MK test**	***t*-test**	**MK test**
Number of stations with no trend	216 (79%)	224 (82%)	52 (98%)	53 (100%)
Number of stations with positive trend	8 (3%)	7 (3%)	0 (0%)	0 (0%)
Number of stations with negative trend	50 (18%)	43 (16%)	1(2%)	0 (0%)
Total number of stations tested	274	274	75	53

The relative magnitude of any trend in AMS for the project area as a whole was also assessed by standard linear regression techniques. AMS were rescaled by corresponding mean annual maximum values and then regressed against time (defined as year of occurrence minus 1900). The regression results from all stations as a group were tested against a null hypothesis of zero serial correlation. Results indicated that the null hypothesis (no trends in AMS in the project area) could not be rejected at 5% significance level.

Because all tests indicated little to no statistically-significant trends in the data, the assumption of stationary climate was accepted for this project area and no adjustment to AMS data was recommended.

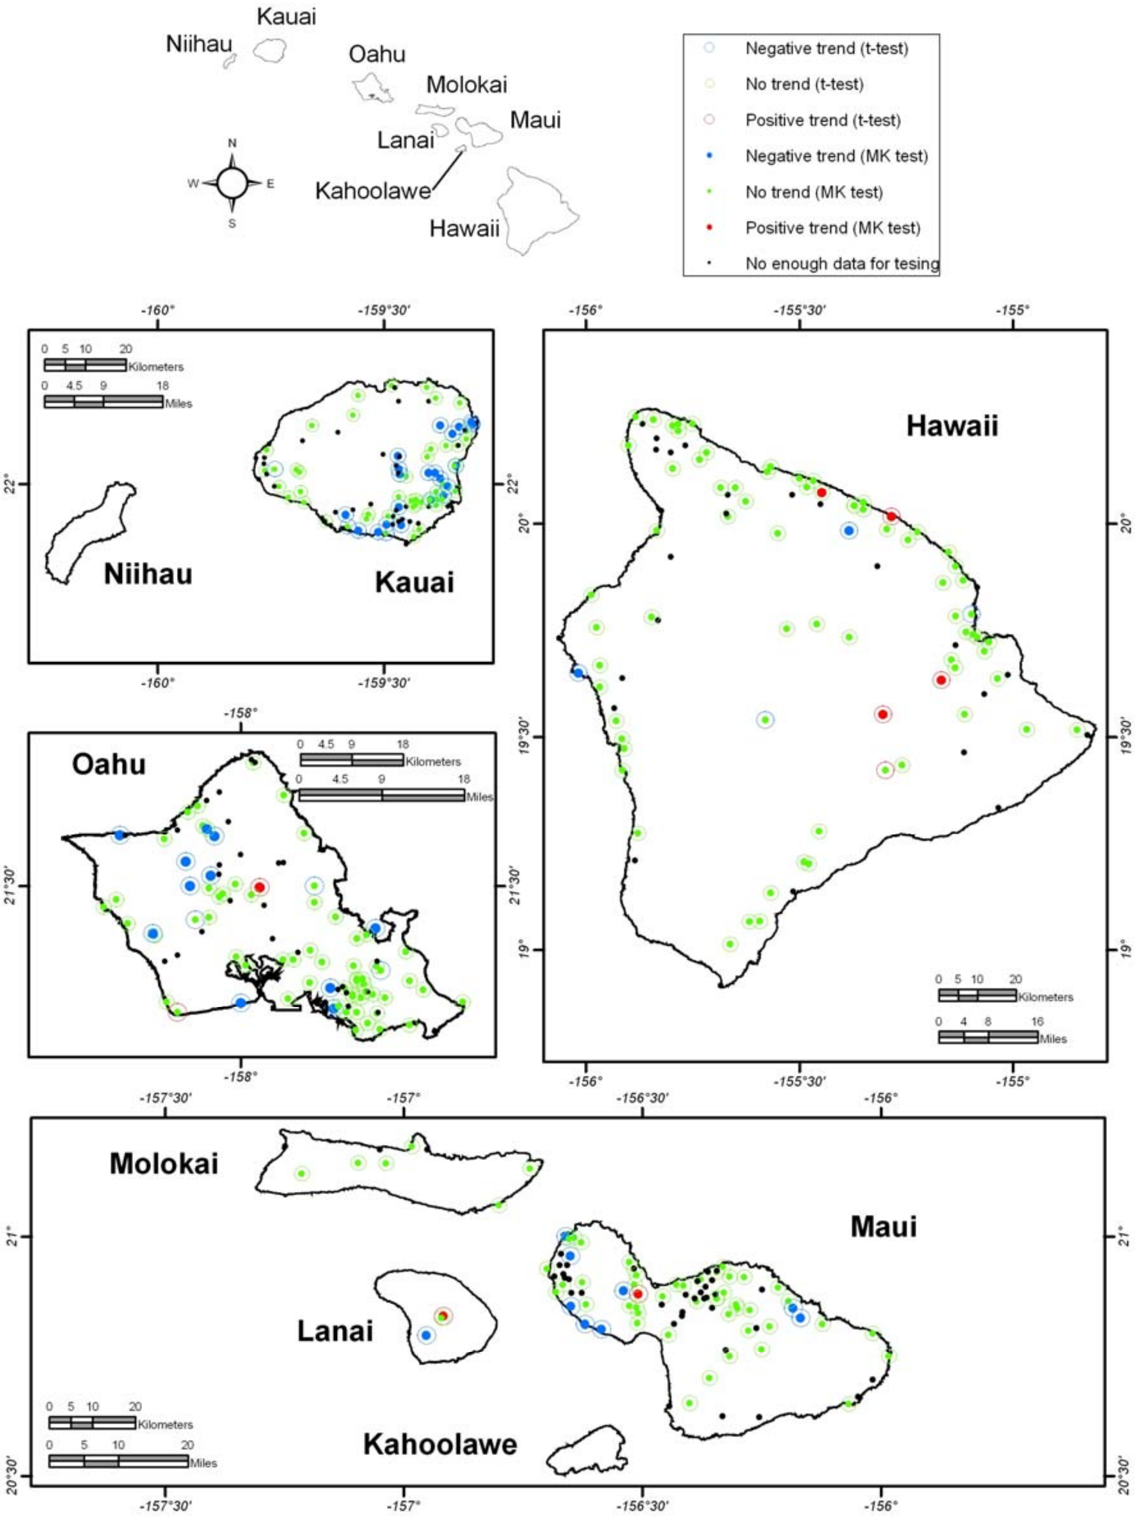

Figure A.2.1. Spatial distribution of trend results for 1-day AMS.

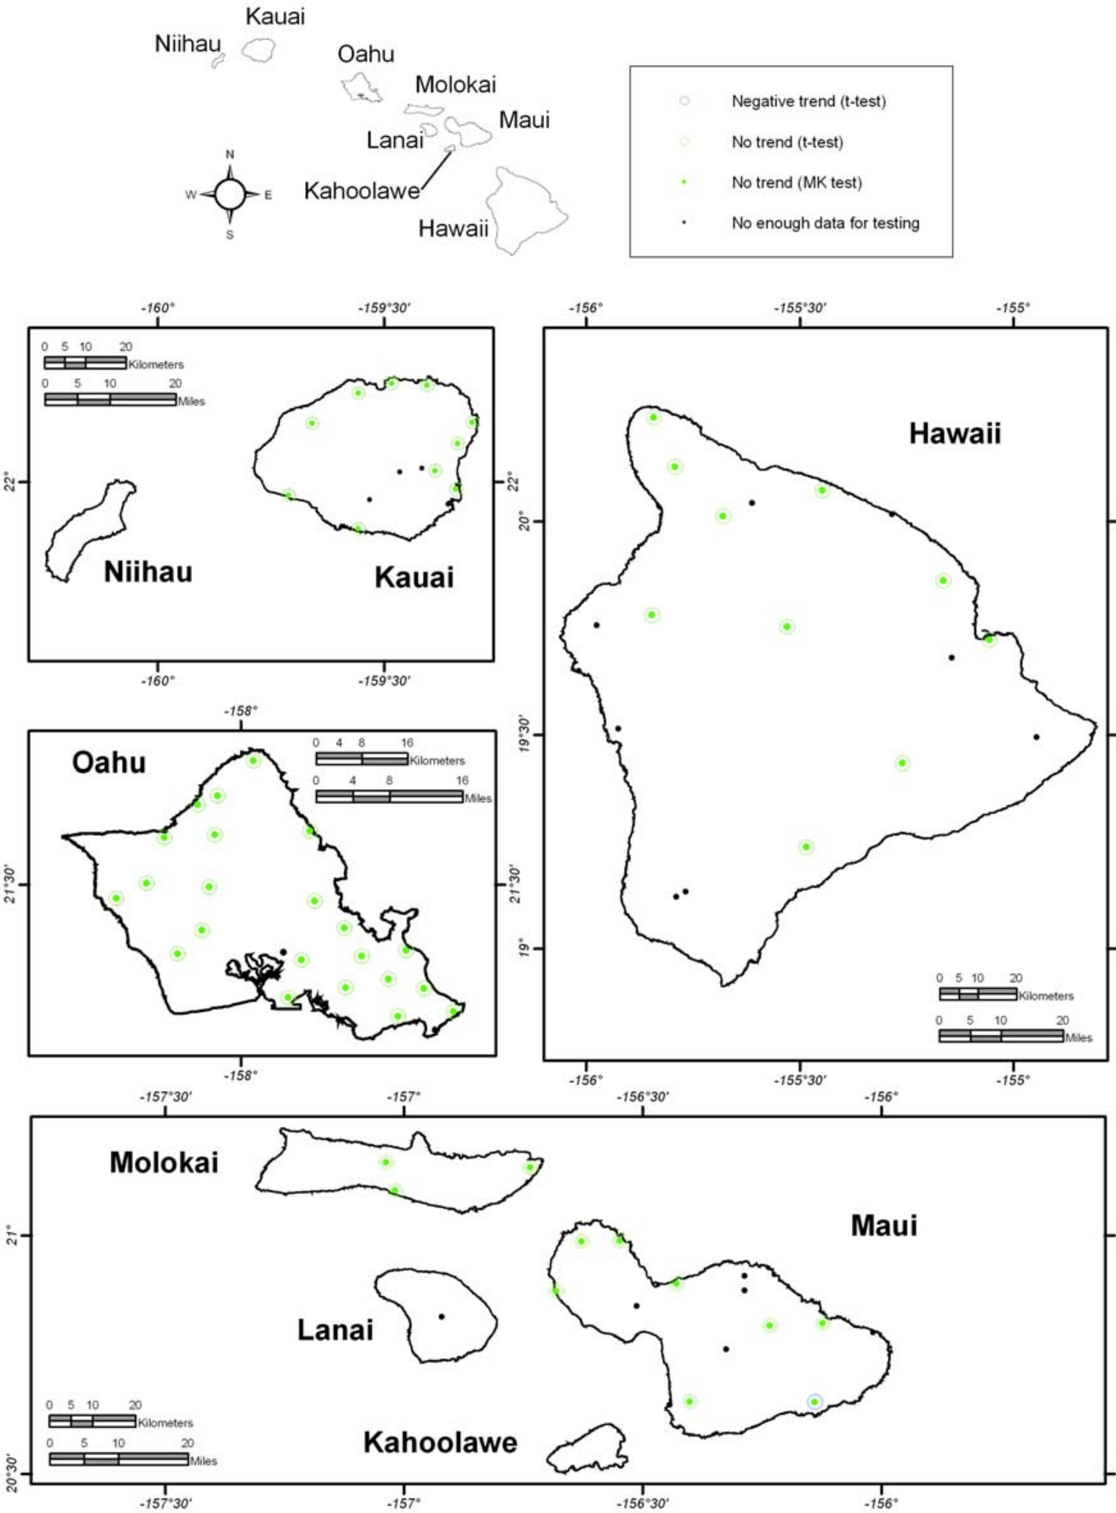

Figure A.2.2. Spatial distribution of trend results for 1-hour AMS.

Appendix A.3 Regional L-moment ratios

Table A.3.1. Number of stations, total number of data years, and regional L-moment ratios: coefficient of L-variation (L-CV), L-skewness and L-kurtosis for each region and daily duration.

Daily region	Duration	Number of stations	Number of data years	L-CV	L-skewness	L-kurtosis

Appendix A.6 PRISM report
(report was formatted by HDSC)

Final Report

Production of Precipitation Frequency Grids for the Hawaiian Islands Using a Specifically Optimized PRISM System

Prepared for
National Weather Service, Hydrologic Design Service Center
Silver Spring, Maryland

Prepared by
Christopher Daly
PRISM Group
Oregon State University

March 2009

1. Project goal

The Hydrometeorological Design Studies Center (HDSC) within the Office of Hydrologic Development of NOAA's National Weather Service is updating precipitation frequency estimates for the Hawaiian Islands. In order to complete the spatial interpolation of point estimates, HDSC requires spatially interpolated grids of MAM precipitation. The contractor, the PRISM Group at Oregon State University (OSU), was tasked with producing a series of grids for precipitation frequency estimation using an optimized system based on the Parameter-elevation Regressions on Independent Slopes Model (PRISM) and HDSC-calculated point estimates for the Hawaiian Islands (HI). The study region excludes the Northwestern Hawaiian Islands (between Kauai and Kure Atoll) because no precipitation data exists for this chain of small islands.

2. Background

HDSC used the mean annual maximum (MAM), approach as described by Hosking and Wallis in "Regional Frequency Analysis; An Approach Based on L-Moments", 1997, to estimate precipitation frequencies. In this approach, the mean of the underlying precipitation frequency distribution is estimated at point locations with a sufficient history of observations. This mean was originally referred to as the "Index Flood," because early applications of the method were used to analyze flood data in hydrology. The form of the distribution and its parameters are estimated regionally. Once the form of the distribution has been selected and its parameters have been estimated, precipitation frequency estimates can be computed from grids of the MAM. The grids that are the subject of this report are spatially interpolated grids of the point estimates of the MAM for various precipitation durations. The point estimates of the MAM were provided by HDSC. HDSC selected an appropriate precipitation frequency distribution along with regionally estimated parameters and used this information with the grids of the MAM to derive grids of precipitation frequency estimates.

The PRISM Group has previously performed similar work to produce spatially interpolated MAM grids for updates of precipitation frequency estimates in the Semiarid Southwest United States, the Ohio River Basin and Surrounding States, and the Puerto Rico/US Virgin Islands study areas.

3. Report

This report describes tasks performed to produce final mean annual maximum (MAM) grids for 14 precipitation durations, ranging from 60 minutes to 60 days, for HI. These tasks were not necessarily performed in this order, nor were they performed just once. The process was dynamic and had numerous feedbacks.

3.1. Adapting the PRISM system

The PRISM modeling system was adapted for use in this project after a small investigation was performed for the Semiarid Southwest United States, and subsequently used in the Ohio River Basin and Surrounding States and Puerto Rico/Virgin Islands study areas. This investigation and adaptation procedure is summarized below.

PRISM is a knowledge-based system that uses point data, a digital elevation model (DEM), and many other geographic data sets to generate gridded estimates of climatic parameters (Daly et al. 1994, 2002, 2003, 2006, 2008) at monthly to daily time scales. Originally developed for precipitation estimation, PRISM has been generalized and applied successfully to temperature, among other parameters. PRISM has been used extensively to map precipitation, dew point, and minimum and maximum temperature over the United States, Canada, China, and other countries. Details on PRISM formulation can be found in Daly et al. (2002, 2003, 2008).

Adapting the PRISM system for mapping precipitation frequencies required an approach slightly different than the standard modeling procedure. The amount of station data available to HDSC for precipitation frequency was much less than that available for high-quality precipitation maps, such as the peer-reviewed PRISM 1971-2000 mean precipitation maps (Daly et al. 2008). Data sources suitable for long-term mean precipitation but not for precipitation frequency included snow courses, short-term COOP stations, remote storage gauges, and others. In addition, data for precipitation durations of less than 24 hours were available from hourly precipitation stations only. This meant that mapping precipitation frequency using HDSC stations would sacrifice a significant amount of the spatial detail present in the 1971-2000 mean precipitation maps.

A pilot project to identify ways of capturing more spatial detail in the precipitation frequency maps was undertaken. Early tests showed that mean annual precipitation (MAP) was an excellent predictor of precipitation frequency in a local area, much better than elevation, which is typically used as the underlying, gridded predictor variable in PRISM applications. In these initial tests, the DEM, the predictor grid in PRISM, was replaced by the official USDA digital map of MAP for the lower 48 states (USDA-NRCS 1998, Daly et al. 2000). Detailed information on the creation of the USDA PRISM precipitation grids is available from Daly and Johnson (1999). MAP was found to have superior predictive capability over the DEM for locations in the southwestern US. The relationships between MAP and precipitation frequency were strong because much of the incorporation of the effects of various physiographic features on mean precipitation patterns had already been accomplished with the creation of the MAP grid from PRISM. Preliminary PRISM maps of 2-year and 100-year, 24-hour precipitation were made for the Semiarid Southwest and compared to hand-drawn HDSC maps of the same statistics. Differences were minimal, and mostly related to differences in station data used.

Further investigation found that the square-root transformation of MAP produced somewhat more linear, tighter and cleaner regression functions, and hence, more stable predictions, than the untransformed values; this transformation was incorporated into subsequent model applications. Square-root MAP was a good local predictor of not only longer-duration precipitation frequency statistics, but for short-duration statistics, as well. Therefore, it was determined that a modified PRISM system that used square-root MAP as the predictive grid was suitable for producing high-quality precipitation frequency maps for this project.

For this study, a previously-developed grid of MAP for HI (1971-2000 averages) was used (Figure 1). This grid was developed under funding from the National Park Service.

3.2. PRISM configuration and operation for the Hawaiian Islands

In general, PRISM interpolation consists of a local moving-window regression function between a predictor grid and station values of the element to be interpolated. The regression function is guided by an encoded knowledge base and inference engine (Daly et al., 2002, 2008). This knowledge base/inference engine is a series of rules, decisions and calculations that set weights for the station data points entering the regression function. In general, a weighting function contains knowledge about an important relationship between the climate field and a geographic or meteorological factor. The inference engine sets values for input parameters by using default values, or it may use the regression function to infer grid cell-specific parameter settings for the situation at hand. PRISM acquires knowledge through assimilation of station data, spatial data sets such as MAP and others, and a control file containing parameter settings.

The other center of knowledge and inference is that of the user. The user accesses literature, previously published maps, spatial data sets, and a graphical user interface to guide the model application. One of the most important roles of the user is to form expectations for the modeled climatic patterns, i.e., what is deemed "reasonable." Based on knowledgeable expectations, the user selects the station weighting algorithms to be used and determines whether any parameters should be changed from their default values. Through the graphical user interface, the user can click on any grid cell, run the model with a given set of algorithms and parameter settings, view the results graphically, and access a traceback of the decisions and calculations leading to the model prediction.

For each grid cell, the moving-window regression function for MAM vs. MAP took the form

$$\text{MAM value} = \beta_1 * \text{sqrt(MAP)} + \beta_0 \qquad (1)$$

where β_1 is the slope and β_0 is the intercept of the regression equation, and MAP is the grid cell value of mean annual precipitation.

Upon entering the regression function, each station was assigned a weight that is based on several factors. For PRISM MAP mapping (used as the predictor grid in this study), the combined weight of a station was a function of distance, elevation, cluster, vertical layer, topographic facet, coastal proximity, and effective terrain weights, respectively. A full discussion of the general PRISM station weighting functions is available from Daly et al. (2008).

Given that the MAP grid incorporated detailed information about the complex spatial patterns of precipitation, in the Hawaiian Islands, only a subset of these weighting functions was needed for this study. For HI, the combined weight of a station was a function of distance, elevation, cluster, respectively. A station is down-weighted when it is relatively distant or has a much different elevation than the target grid cell, or when it is clustered with other stations (which can lead to over-representation).

The moving-window regression function was populated by station data provided by the HDSC. A PRISM GUI snapshot of the moving-window relationship between MAP and 24-hour MAM in western Maui is shown in Figure 2.

There were little station data available for durations of 12 hours or less from which to perform the interpolation. In addition, it was clear that the spatial patterns of durations of 12 hours or less could be very different than those of durations of 24 hours or more. This issue was encountered in a previous study for Puerto Rico. During that study the following procedure was developed, and adopted here:

(1) Convert available ≤ 12-hour station values to an MAM/24-hr MAM ratio (termed R24) by dividing by the 24-hour values;

(2) using the station R24 data in (1), interpolate R24 values for each ≤ 12-hour duration (60 minutes, and 2, 3, 6, and 12 hours) using PRISM in inverse-distance weighting mode;

(3) using bi-linear interpolation from the cells in the R24 grids from (2), estimate R24 at the location of each station having data for ≥ 24-hour durations only;

(4) multiply the estimated R24 values from (3) by the 24-hour value at each ≥ 24-hour station to obtain estimated ≤ 12-hour values;

(5) append the estimated stations from (4) to the ≤ 12-hour station list to generate a station list that matches the density of that for ≥ 24 hours; and

(6) interpolate MAM values for ≤ 12-hour durations with PRISM, using MAP as the predictor grid.

Investigation of the little available data failed to provide convincing evidence that the spatial patterns of R24 values were strongly affected by MAP, coastal proximity, topographic facets, or other factors. Therefore, the slope of the moving-window regression function for R24 vs. MAP of the form

$$R24 = \beta_1 * \mathrm{sqrt}(MAP) + \beta_0 \tag{2}$$

was forced to zero everywhere. This meant that the interpolated value of R24 was a function of distance and cluster weighting only (essentially inverse-distance weighting).

Relevant PRISM parameters for applications to 60-minute R24 and 24-hour MAM statistics are listed in Tables 1 and 2, respectively. Further explanations of these parameters and associated equations are available in Daly et al. (2002, 2008). Input parameters used for the 60-minute R24 application were generally applied to all durations for which it was applied (less than or equal to 12 hours). The 24-hour MAM input parameters were generally applied to all durations.

The values of radius of influence (*R*), the minimum number of total (s_t) stations required in the regression were based on information from user assessment via the PRISM graphical user interface, and on a jackknife cross-validation exercise, in which each station was deleted from the data set one at a time, a prediction made in its absence, and mean absolute error statistics compiled (see Results section).

The input parameter that changed readily among the various durations was the default slope (β_{1d}) of the regression function. Slopes are expressed in units that are normalized by the average observed value of the precipitation in the regression data set for the target cell. Evidence gathered during PRISM model development indicates that this method of expression is relatively stable in both space and time (Daly et al., 1994).

Bounds are put on the slopes to minimize unreasonable slopes that might occasionally be generated due to local station data patterns; if the slope is out of bounds and cannot be brought within bounds by the PRISM outlier deletion algorithm, the default slope is invoked (Daly et al., 2002). The maximum slope bound was set to a uniformly high value of 30.0, to accommodate a large range of valid slopes; lower values were not needed to handle extreme values, because all values were within reasonable ranges. Slope default values were based on PRISM diagnostics that provided information on the distribution of slopes across the modeling region. The default value was set to approximate the average regression slope calculated by PRISM. For these applications, default slopes typically increased with increasing duration (Table 3). In general, the longer the duration, the larger the slope.

This is primarily a result of higher precipitation amounts at the longer durations, and the tendency for longer-duration MAM statistics to bear a stronger and steeper relationship with MAP than shorter-duration statistics.

3.3. Review of draft grids

Draft grids for the 60-minute, 12-hour, 24-hour and 10-day durations were produced and made available to HDSC for evaluation. All of the necessary station data were provided by HDSC. The review process was coordinated and undertaken by HDSC in which specific comments, submissions of additional station data information, and the identification of questionable data and spatial patterns were requested. In all, four sets of draft grids were produced during this process.

Most subsequent changes to the draft grids involved omitting and adding stations to the data set, based on map examination and quality control procedures by both the PRISM Group and HDSC. The review process also resulted in two changes to the mapping methodology:

(1) Restriction of the elevation range over which stations are included in the moving-window regression function. In the rain shadow of northwestern Hawaii along the coastline, interpolated MAM was too low, due to an overly steep MAM vs. MAP regression slope calculated from nearby, high-elevation stations. Restricting the upward-looking elevation range to 100 m, but keeping the downward-looking range unrestricted, effectively limited the slope calculation to nearby dry, coastal stations, and produced more reasonable interpolated values.

(2) A revision of the MAP grid to include hourly precipitation station Pohakuloa (COOP ID 51-8063, elevation 1985 m), on the southwest slope of Mauna Kea. Pohakuloa was exhibiting lower MAM values than were reasonable for the gridded MAP for that location. Given that this area was in a steep precipitation gradient, and that the data quality at Pohakuloa appeared to be good, the station was added and the MAP grid re-modeled with PRISM. The resulting grid had a lower MAP in this area, and provided a better match for the MAM values.

3.4. Final grids

Before delivering the final grids to HDSC, the PRISM Group checked them for internal consistency. In other words, the value of the MAM at each grid point for each duration must be less than/or equal to the value for lower durations at the same grid point. If an error of this nature occurs, the current convention is to set the longer duration to a slightly higher value than the lower duration using post-processing tools created by the PRISM Group for previous projects.

The final delivered grids inherited the spatial resolution of the latest 1971-2000 PRISM mean annual precipitation grids for the Hawaiian Islands, which is 15 arc-seconds (~450 meters). The grid cell units are in mm*100. Final MAM grids delivered to HDSC are as follows:

60-minute
120-minute
3-hour
6-hour
12-hour
24-hour
48-hour
4-day

7-day
10-day
20-day
30-day
45-day
60-day
Total: 14

3.5. Performance evaluation

PRISM cross-validation statistics for 60-minute/24-hour MAM ratio and the 60-minute and 24-hour MAM intensities were compiled and summarized in Table 4. These errors were estimated using an omit-one bootstrap method, where each station is omitted from the data set, estimated in its absence, then replaced. Since the 60-minute/24-hour MAM ratio was expressed as a percent, the percent bias and mean absolute error are the given as the bias and MAE in the original percent units (not as a percentage of the percent).

Overall bias and mean absolute error (MAE) were less than 1 percent for the 60-minute/24-hour MAM ratio. For the 60-minute and 24-hour MAM intensities, biases were also very low (< 1 percent), and MAE was slightly less than 10 percent. Errors for 2- to 12-hour durations were similar to those for the 60-minute duration, with biases ranging from 0.5 to 0.8 percent, and MAEs ranging from 9.5 to 9.6 percent. Errors for 2 to 60-day durations were similar to those for the 24-hour duration, with biases ranging from 0.3-1.8 percent, and MAEs from 9.6 to 11.5 percent. Given the lack of data, one would have expected the 60-minute to 12-hour MAM errors to be somewhat higher than those for the 24-hour to 60-day MAMs. A likely reason for this is that the addition of many synthesized stations, derived from a PRISM interpolation of R24 values, resulted in a station data set that was spatially consistent, and thus, somewhat easier to interpolate with each station deleted from the data set. Therefore, there is little doubt that the true interpolation errors for the 60-minute MAM are higher than those shown in Table 4.

Name	Description	Value
<u>Regression Function</u>		
R	Radius of influence	5 km*
s_t	Minimum number of total stations desired in regression	15 stations
β_{1m}	Minimum valid regression slope	0.0[+]
β_{1x}	Maximum valid regression slope	0.0[+]
β_{1d}	Default valid regression slope	0.0[+]
<u>Distance Weighting</u>		
A	Distance weighting exponent	2.0
F_d	Importance factor for distance weighting	1.0
D_m	Minimum allowable distance	0.0 km
<u>Elevation Weighting</u>		
B	MAP weighting exponent	NA/NA
F_z	Importance factor for MAP weighting	NA/NA
$\Delta\square z_m$	Minimum station-grid cell MAP difference below which MAP weighting is maximum	NA/NA
Δz_x	Maximum station-grid cell MAP difference above which MAP weight is zero	NA/NA

* Expands to encompass minimum number of total stations desired in regression (s_t).

[+] Slopes are expressed in units that are normalized by the average observed value of the precipitation in the regression data set for the target cell. Units here are 1/[sqrt(MAP(mm))*1000].

Table 2. Values of relevant PRISM parameters for modeling of 24-hour mean annual maximum statistics for the Hawaiian Islands. See Daly et al. (2002) for details on PRISM parameters.

Name	Description	Value
Regression Function		
R	Radius of influence	5 km*
s_t	Minimum number of total stations desired in regression	15 stations
β_{1m}	Minimum valid regression slope	0.0$^+$
β_{1x}	Maximum valid regression slope	30.0$^+$
β_{1d}	Default valid regression slope	2.8$^+$
Distance Weighting		
A	Distance weighting exponent	2.0
F_d	Importance factor for distance weighting	1.0
D_m	Minimum allowable distance	0.0 km
Elevation Weighting		
B	Elevation weighting exponent	0.0
F_z	Importance factor for elev weighting	0.0
Δ□z_m	Minimum station-grid cell elev difference below which MAP weighting is maximum	NA
Δz_x	Maximum station-grid cell elevation difference above which station is eliminated from data set	100 m upwards, 5000 m downwards

* Expands to encompass minimum number of total stations desired in regression (s_t).

$^+$ Slopes are expressed in units that are normalized by the average observed value of the precipitation in the regression data set for the target cell. Units here are 1/[sqrt(MAP(mm))*1000].

Table 3. Values of PRISM slope parameters for modeling of MAM statistics for the Hawaiian Islands for all durations. For durations of 12 hours and below, station data were expressed as the ratio of the given duration's MAM value to the 24-hour MAM value, and interpolated; this was followed by an interpolation of the actual MAM values. See text for details. See Table 1 for definitions of parameters.

	Hawaiian Islands		
Duration	β_{1m}	β_{1x}	β_{1d}

Appendix A.7 Peer review comments and responses

The Hydrometeorological Design Studies Center (HDSC) conducted a peer review of the Hawaiian Islands precipitation frequency project during the period September 22, 2008 to October 31, 2008. The review included the following items:

1. Depth-duration-frequency curves at stations derived from annual maximum series data;
2. Maps of spatially-interpolated mean annual maximum precipitation amounts for 60-minute, 12-hour, 24-hour, and 10-day durations;
3. Isohyetal maps of precipitation frequency estimates for 1/2 and 1/100 annual exceedance probabilities and for 60-minute, 12-hour, 24-hour, and 10-day durations;
4. Maps showing regional groupings of stations used in frequency analysis for daily durations (≥ 24-hour) and hourly durations (< 24-hour).

HDSC requested comments from approximately 115 individuals. Six reviews were received, some of which represented consolidated feedback from several individuals. This document presents a consolidation of all review comments collected during the 6-week review period and HDSC's responses. Similar issues/comments were grouped together and are accompanied by a single HDSC response. The comments and their respective HDSC responses have been divided into three categories:

1. Comments pertaining to regionalization;
2. Comments pertaining to mean annual maximum precipitation and precipitation frequency grids/maps;
3. General questions and comments.

1. Comments pertaining to regionalization

1.1 In some cases, the identified regions appear to include only 1 or 2 stations. It is unclear how the region boundaries were drawn on the basis of such limited data, particularly for durations less than 24 hours.

HDSC response: Homogeneous regions were created based on a variety of statistical tests and climatological considerations. Some regions only comprise of a few stations in order to accurately represent local climate.

1.2 The regional zones look ok following the adjustments since Geoff's visit here.

HDSC response: We agree.

2. Comments pertaining to mean annual maximum precipitation and precipitation frequency grids/maps

2.1 The precipitation frequency maps appear to extend offshore in areas where no data are available. In some cases, the interpolation scheme provides the appearance of detail offshore that may not be justified (see for example the small 3.2 inch contour on the 100-year, 60-minute map of northern Oahu near Mokuleia, or the 8-inch contour on the 100-year, 24-hour map of southern Maui near La Perouse Bay). In these cases, would it be desirable to clip the estimates at the coast?

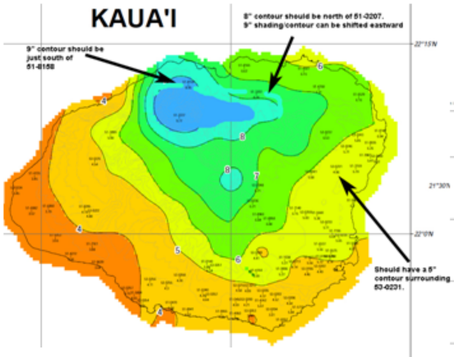
HDSC response: The final maps/grids were masked to match the coastline.

2.2 In general, I don't have any issues with the maximum and minimum values plotted on each map. The east Maui maxima are eye-opening but mainly because they're unexpected to me and not because I don't believe them. If that's what the data show, then that's what it is.

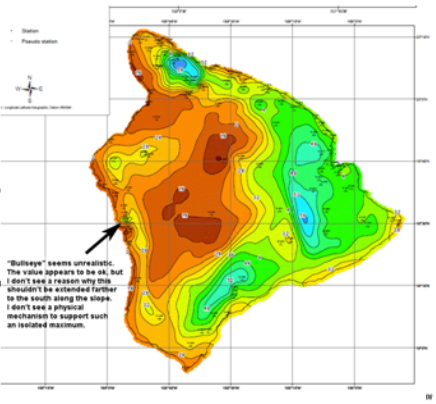
I'm a little concerned about the maximum across eastern Maui. I wouldn't think the rainiest place on Maui would be THAT much rainier than the rainiest place on the Big Island, Oahu or Kauai. For example, at 100y24h there is a max of 38 inches on Maui but only 28 on the big island and 24 on Oahu and Kauai. I'm concerned that lack of data on the other islands is reducing the maximums there. Is it lack of data in critical areas that is keeping the maxes on other Islands lower or are the conditions that different? I don't think the conditions are that different? One could look at types of vegetation on the upslope sides on each of the islands for instance. Is the Halenet data being used for regional growth factors on the other islands? What about the means? This large difference concerns me.

HDSC response: The high values on the eastern slopes and higher terrain of Maui in the peer-reviewed maps were driven by the relatively new Haleakala Climate Network (HaleNet), which consists of climate stations along the leeward and windward slopes of the Haleakala volcano. HaleNet was established in 1988-90 with a number of stations on the relatively dry west-northwest facing (leeward) slope. Then in 1992, additional stations were installed at remote locations along the windward slopes of Haleakala. The records at some of these stations are relatively short. The PRISM mean annual precipitation (MAP) grid, which serves as a predictor layer for the mean annual maximum maps, included the HaleNet stations. Comparatively, although Oahu is surprisingly data sparse on the crest of the windward range, the influence of the MAP grid already contributes to high precipitation frequency (PF) estimates in these areas. The Big Island also has a good deal of un-reported territory as well, so some surprises could exist there; however the 24-hour PF estimates are already higher than those in TP43. We have reviewed the pattern and magnitude of the PF estimates in eastern Maui relative to the other islands and made some changes. Given the short records and disproportionate influence of HaleNet stations on the precipitation frequency spatial patterns due to the lack of stations in general, the decision was made to include only one HaleNet station, Big Bog. We also developed estimates at "pseudo" stations in western Maui and central Kauai to anchor the spatial patterns and magnitudes of the estimates there based on expectations.

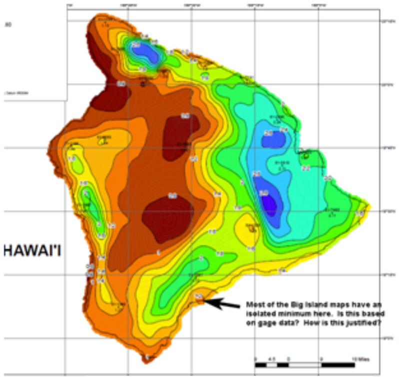
2.3 I noticed there were some quirks with the contouring. For example, there are several instances of max and min "bullseyes" that appear to be based solely on the value from a single gage station. That's fine to me, but there are also instances where the contouring ignores the plotted value at a gage site so there's inconsistency in the convention used. See the images below for examples.



24-hour MAM



100-year 60-minute



60-minute MAM

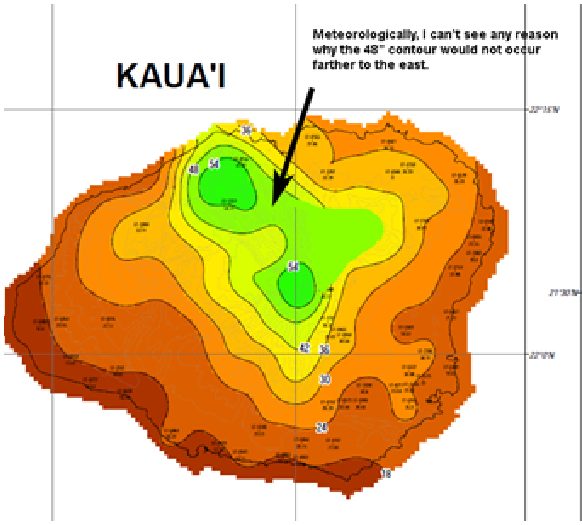
HDSC response: The isolated minimum on the southeastern coast of the Big Island is associated with a minimum on the PRISM mean annual precipitation grid, which was used in the interpolation of the mean annual maxima grids/maps. Although we don't have a gauge for frequency analysis at this location, it is possible PRISM did. Although every attempt is made to ensure the contours are consistent with the plotted station data, there are times when the spatial interpolation deviates to instill climatological consistency and smooth contours. In the final deliverable, the spatially interpolated values at stations are published; it's only during the peer review that the actual gauge-based data are plotted.

The 100-year 60-minute bulls eye on the northern Kona Coast (on the Big Island) is the result of erroneous precipitation frequency estimates at the "pseudo" stations around station 51-3987 (KEALAKEKUA 4 74.8). The "pseudo" stations are locations where hourly PF estimates were developed at daily-only gauge locations to anchor interpolation. This was remedied in the final maps.

2.4 Many of the precipitation frequency maps appear to include contours over small areas that are apparently influenced heavily by a single station. For example, on the 100-year, 12-hour precipitation map for Oahu, a small contour is drawn near Barbers Point at the southwestern point of the island. In other cases, the small, closed contours contain no stations (see for example the 42 inch contour on the 100-year, 10-day map for eastern Kauai). Although these contours likely are related to the contouring scheme used, is this amount of detail justified? Is there a way to spatially show the uncertainty in the estimates?

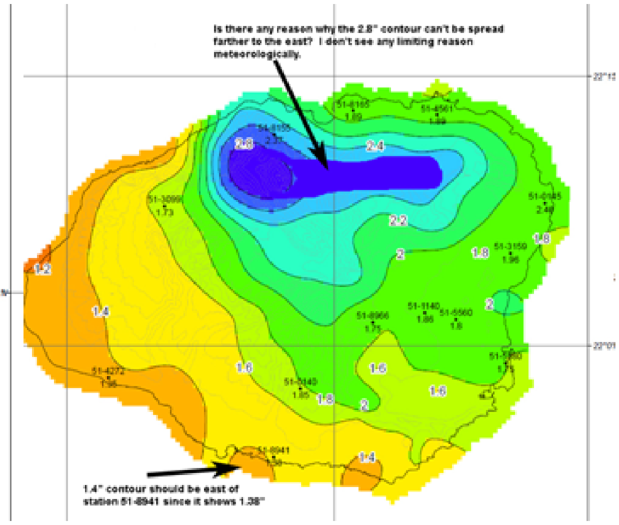
HDSC response: In areas with few stations, the spatial interpolation is not constrained by nearby stations and therefore can sometimes develop a radius of influence around stations. We tried not to mitigate these issues at the expense of smoothing out spatial detail where we thought it was appropriate (e.g., reliable station, complex terrain). The chosen contouring intervals can also sometimes give a false sense of more variation than exists in reality; we tried our best to identify those cases and to eliminate them. The final precipitation frequency Atlas for the Hawaiian Islands contains upper and lower confidence limits for the point precipitation frequency estimates. We do not depict the uncertainty spatially.

2.5 As indicated in some of the attached graphics, the maxima along the north slope of Kauai appear to be focused too much in the northwest side due to the influence of gage 51-2227. I don't disbelieve maxima at this gage, I just feel the higher values should be extended eastward. I see no meteorological or climatological reason why this wouldn't be the case.



Meteorologically, I can't see any reason why the 48" contour would not occur farther to the east.

100-year 10-day



Is there any reason why the 2.8" contour can't be spread farther to the east? I don't see any limiting reason meteorologically.

1.4" contour should be east of station 51-8941 since it shows 1.38"

60-minute MAM

HDSC response: The lack of reliable data in the remote area of central Kauai has made modeling this area challenging. In response to your comments and an internal investigation, we made two changes to improve estimates in this area. We decided to add a "pseudo" station (station ID 51-6565) to the top of Mt. Waialeale, which is among one of the wettest places on earth. This station didn't have sufficient data to be included in frequency analysis, but based on its limited data, spatially interpolated values, and TP-43/51, we've been able to estimate mean annual maximum and PF estimates for this location. In addition, investigation found that station 51-8155 in north central Kauai near the coast was better regionalized for precipitation frequency analysis in daily region 14 than region 8. These changes improved the spatial patterns in this area so that they are more consistent with expectations.

3. General questions and comments

3.1 Having a separate web page for each island group is a good idea. However, in the text file saved from each island, the island name is placed where the state name should be.

HDSC response: In the final deliverable we ensured the state name is included in the title.

3.2 I would suggest treating Hawaii different from the other states by having an intermediate web page. For example, from the general US map, if a user selects Hawaii, go to a page with a map of Hawaii. From there, let the user select the particular island of interest. Then go to the island web page.

HDSC response: We created an interim web page for Hawaii on the general PFDS map of the United States. From that page, users can select the specific island they want to visit.

3.3 Web page for Kauai: some of the station symbols (red squares) overlap so much that you cannot see the station name for the underlying symbol. This only occurs in two places (shown by the arrows in the following images).

HDSC response: We recognized the problem. However, that functionality was in place only for the peer review.

3.4 Web page for Oahu: 2.2 Select site from list of stations, stations are suggested to be in alphabetical order.

HDSC response: Stations are now sorted in alphabetical order.

3.5 I think the drafts look good overall and it definitely is great to see the light at the end of the tunnel!

HDSC response: We agree.

3.6 I suggest you remove Molokini Island from the Maui maps. The island is very small and is uninhabited.

HDSC response: Per this suggestion we masked out Molokini Island.

Appendix A.8 Temporal distributions of annual maxima

1. Introduction

Temporal distributions of annual maxima with less than 50% chance of being exceeded in any year are provided for 6-, 12-, 24-, and 96-hour durations. The temporal distributions are expressed in probability terms as cumulative percentages of precipitation totals at various time steps. To provide detailed information on the varying temporal distributions, separate temporal distributions were also derived for four precipitation cases defined by the duration quartile in which the greatest percentage of the total precipitation occurred.

2. Methodology and results

The methodology used to produce the temporal distributions is similar to the one developed by Huff (1967) except in the definition of precipitation cases. Precipitation cases for the temporal distribution analysis were selected from the annual maximum series used in the precipitation frequency analysis. Each case (i.e., maxima) was the total accumulation over a selected specific duration (6-, 12-, 24-, or 96-hour). Therefore, precipitation cases for this analysis may contain parts of one or more storms. Because of that, temporal distribution curves presented here will be different from corresponding temporal distribution curves obtained from the analysis of single storms. Also, precipitation cases always start with precipitation but not necessarily end with precipitation resulting in potentially more front-loaded cases when compared with distributions derived from the single storm approach. Only annual maxima with no more than 1 in 2 or 50% chance of being exceeded in any year were included. Table A.8.1 shows the number of precipitation cases used to derive the temporal distributions for each duration.

For each precipitation case, precipitation accumulation was converted into a percentage of the total precipitation amount at one hour time increments. All cases for a specific duration were then combined from all stations in the project area and probabilities of occurrence of precipitation totals were computed at each hour. The temporal distribution curves for nine deciles (10% to 90%) were smoothed using a linear programming method (Bonta and Rao, 1988) and plotted in the same graph. Figure A.8.1 shows temporal distribution curves for the four selected durations; time steps were converted into percentages of durations for easier comparison.

The cases were further divided into four categories by the quartile in which the greatest percentage of the total precipitation occurred. Table A.8.1 shows the numbers and proportion of precipitation cases used to derive the temporal distributions for each quartile. Unlike the cases of 12-, 24-, and 96-hour durations in which the number of data points can be equally divided by four, the cases of 6-hour duration contain only six data points and they cannot be evenly distributed into four quartiles. Therefore, in this analysis, for 6-hour duration, the first quartile contains precipitation cases where the most precipitation occurred in the first hour, the second quartile contains precipitation cases where the most precipitation occurred in the second and third hours, the third quartile contains precipitation cases where the most precipitation occurred in the fourth hour, and the fourth quartile contains precipitation cases where the most precipitation occurred in the fifth and sixth hours. This uneven distribution affects the number of cases contained in each quartile for the 6-hour duration. Figures A.8.2 through A.8.5 show the temporal distribution curves for four quartile cases for 6-hour, 12-hour, 24-hour and 96-hour durations, respectively, where the time steps on the x-axis are in hours.

Table A.8.1. Number of all precipitation cases and number (and percent) of cases in each quartile for selected durations.

Duration (hours)	All cases	First-quartile cases	Second-quartile cases	Third-quartile cases	Fourth-quartile cases
6	2643	274 (10%)	1341 (51%)	245 (9%)	783 (30%)
12	2645	911 (34%)	743 (28%)	572 (22%)	419 (16%)
24	2638	1018 (39%)	662 (25%)	512 (19%)	446 (17%)
96	2639	1084 (41%)	590 (23%)	509 (19%)	456 (17%)

Temporal distribution data are available from the Precipitation Frequency Data Server in a tabular format for any location under the 'Supplementary information' tab or through the temporal distribution web page (http://hdsc.nws.noaa.gov/hdsc/pfds/pfds_temporal.html). For 6-, 12- and 24-hour durations, temporal distribution data are provided in 0.5-hour increments and for 96-hour duration in hourly increments.

3. Interpretation

Figure A.8.1 shows the temporal distribution curves of annual maxima with less than 50% chance of being exceeded in any year for the 6-, 12-, 24-, and 96-hour durations for the project area. Figures A.8.2 through A.8.5 show temporal distribution curves for first-, second-, third-, and fourth-quartile cases for 6-hour, 12-hour, 24-hour and 96-hour durations, respectively. First-quartile plots show temporal distribution curves for cases where the greatest percentage of the total precipitation fell during the first quarter of the duration (e.g., the first 3 hours of a 12-hour duration). The second, third, and fourth quartile plots are similarly for cases where the most precipitation fell in the second, third, or fourth quarter of the duration.

The temporal distribution curves represent the averages of many cases and illustrate the temporal distribution patterns with 10% to 90% occurrence probabilities in 10% increments. For example, the 10% curve in any figure indicates that 10% of the corresponding precipitation cases had distributions that fell above and to the left of the curve. Similarly, 10% of the cases had temporal distribution falling to the right and below the 90% curve. The 50% curve represents the median temporal distribution.

The following is an example of how to interpret the results using the figure (a) in the upper left panel of Figure A.8.4 and information from Table A.8.1 for 24-hour first-quartile cases.

- Of the total of 2,638 24-hour cases, 1,018 (39%) of them were first-quartile.
- In 10% of the first-quartile cases, 50% of the total precipitation fell by the 3rd hour and 90% of the total precipitation fell by 7.5 hours.
- A median case of this type will drop half of the precipitation (50% on the y-axis) in approximately 5.5 hours.
- In 90% of the cases, 50% of the total precipitation fell by less than 10 hours and 90% of precipitation fell by 22.5 hours.

Temporal distribution curves are provided in order to show the range of possibilities. Care should be taken in the interpretation and use of temporal distribution curves. For example, the use of different temporal distribution data in hydrologic models may result in very different peak flow estimates. Therefore, they should be selected and used in a way to reflect users' objectives.

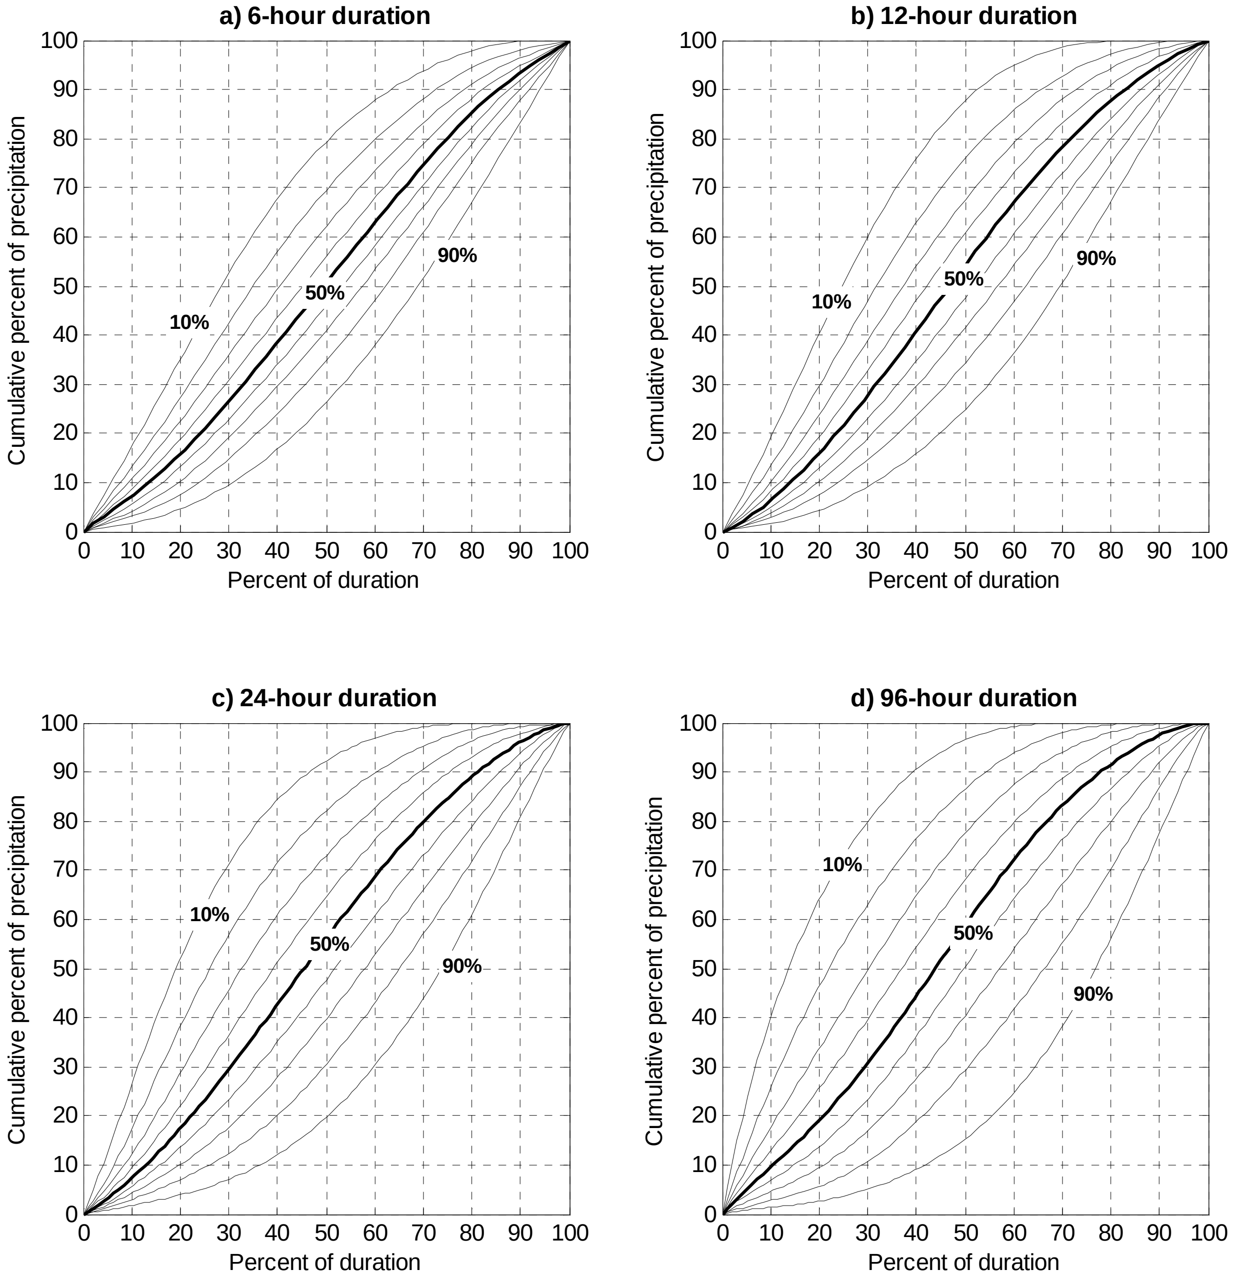


Figure A.8.1. Temporal distribution curves for all cases for: a) 6-hour, b) 12-hour, c) 24-hour, and d) 96-hour durations.

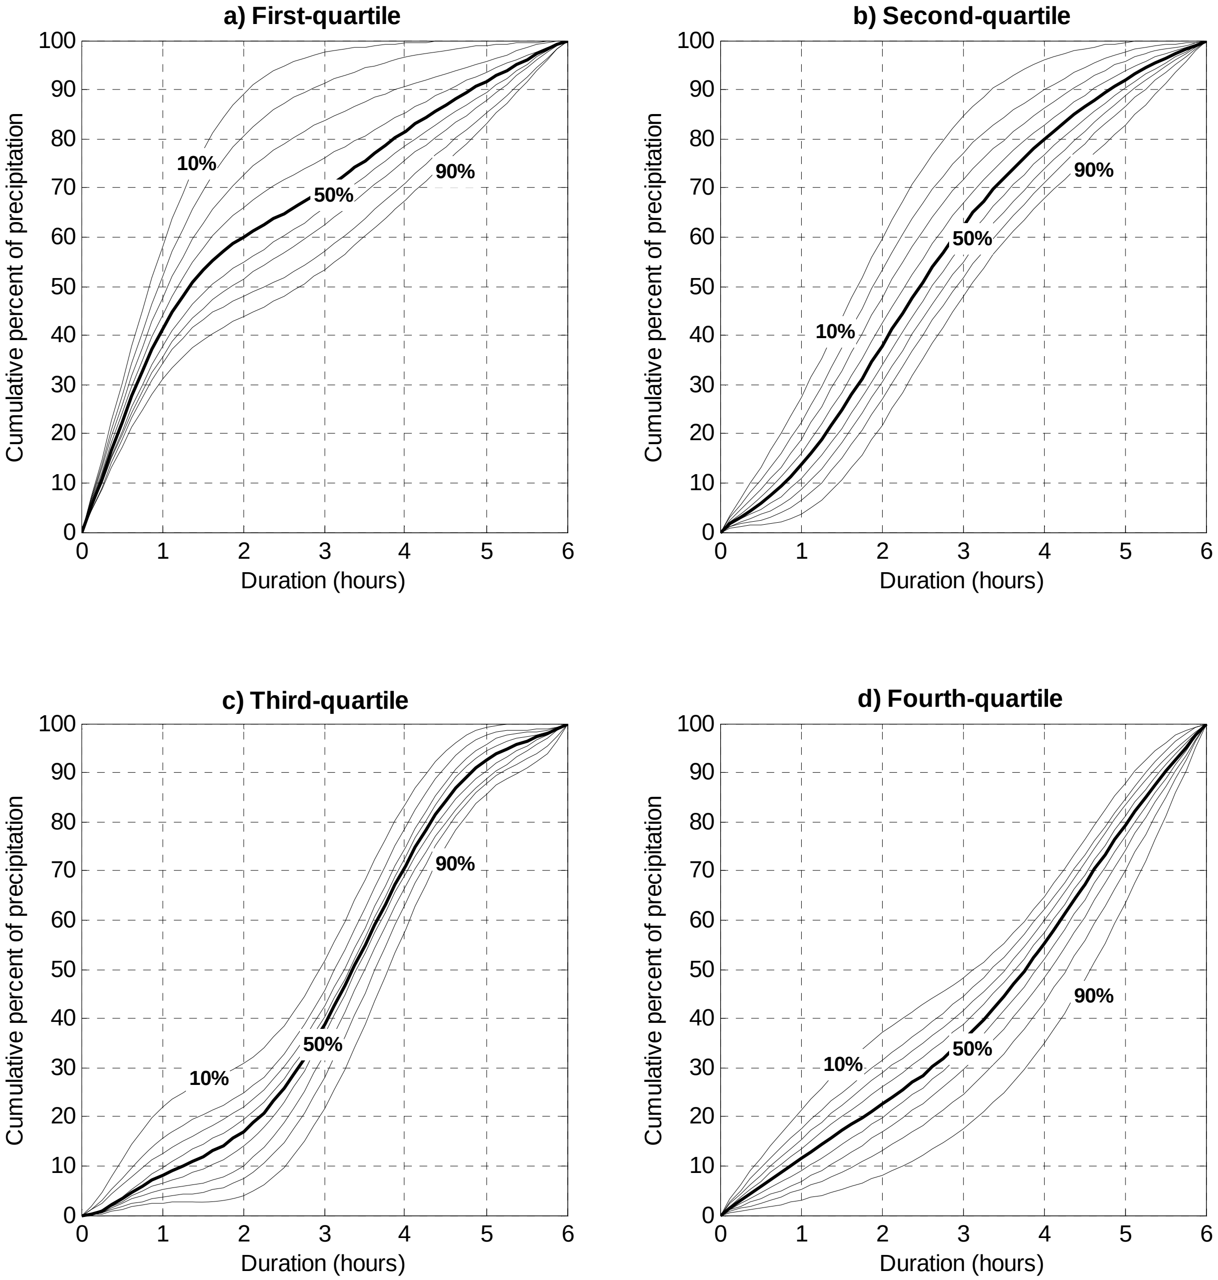

Figure A.8.2. 6-hour temporal distribution curves for: a) first-quartile, b) second-quartile, c) third-quartile, and d) fourth-quartile cases.

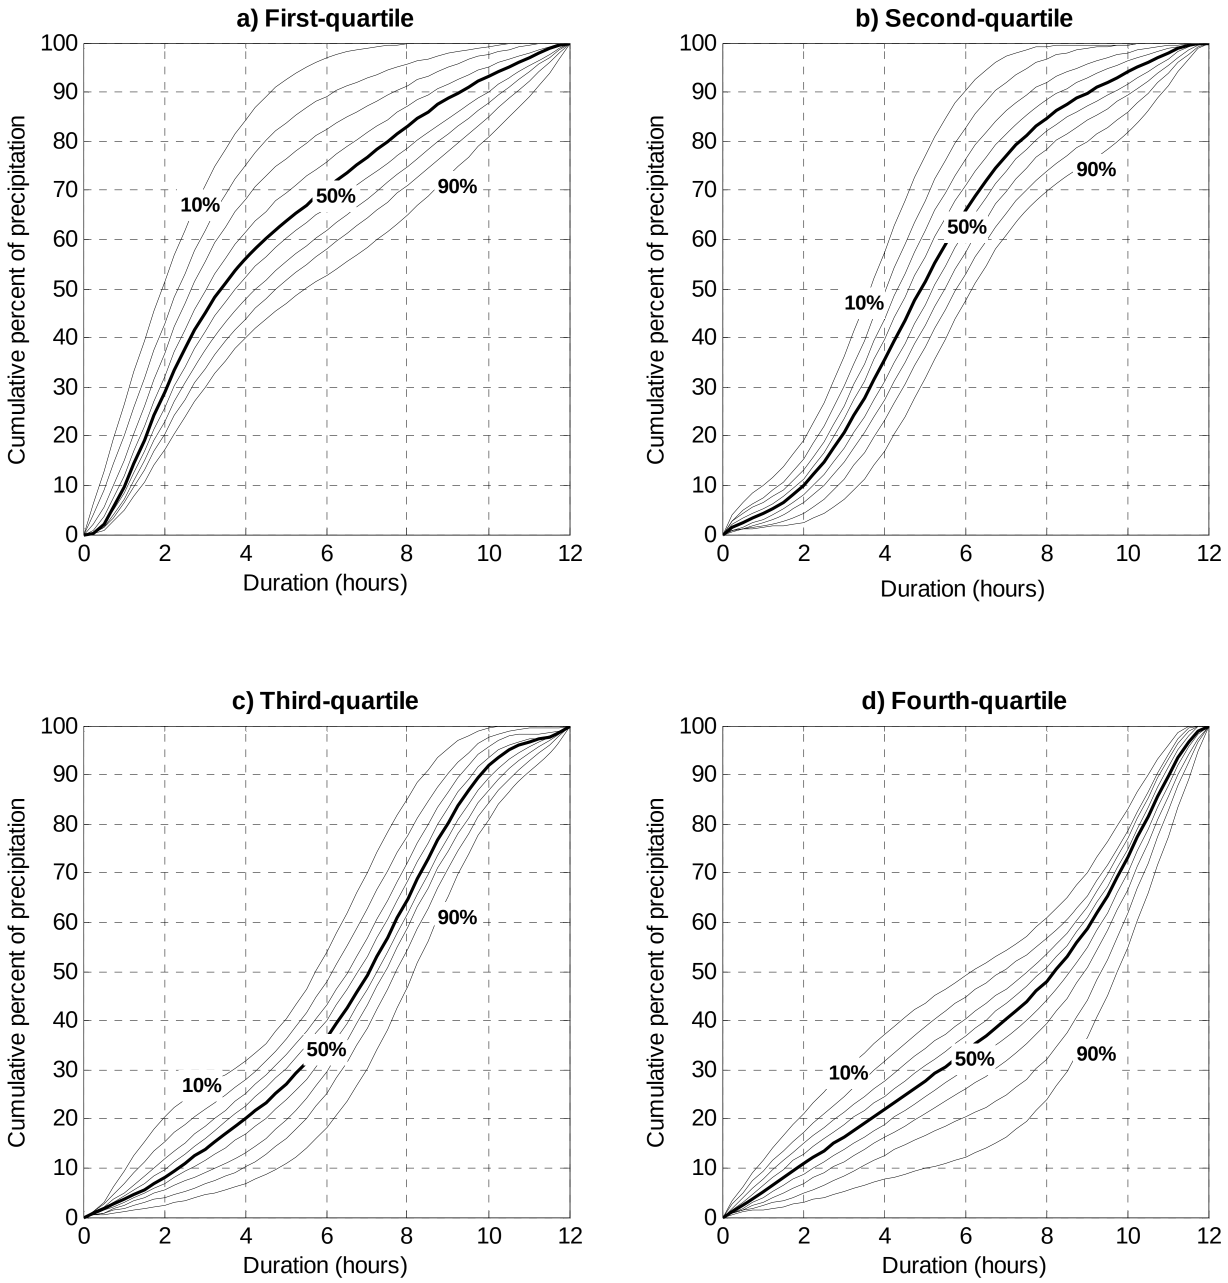

Figure A.8.3. 12-hour temporal distribution curves for: a) first-quartile, b) second-quartile, c) third-quartile, and d) fourth-quartile cases.

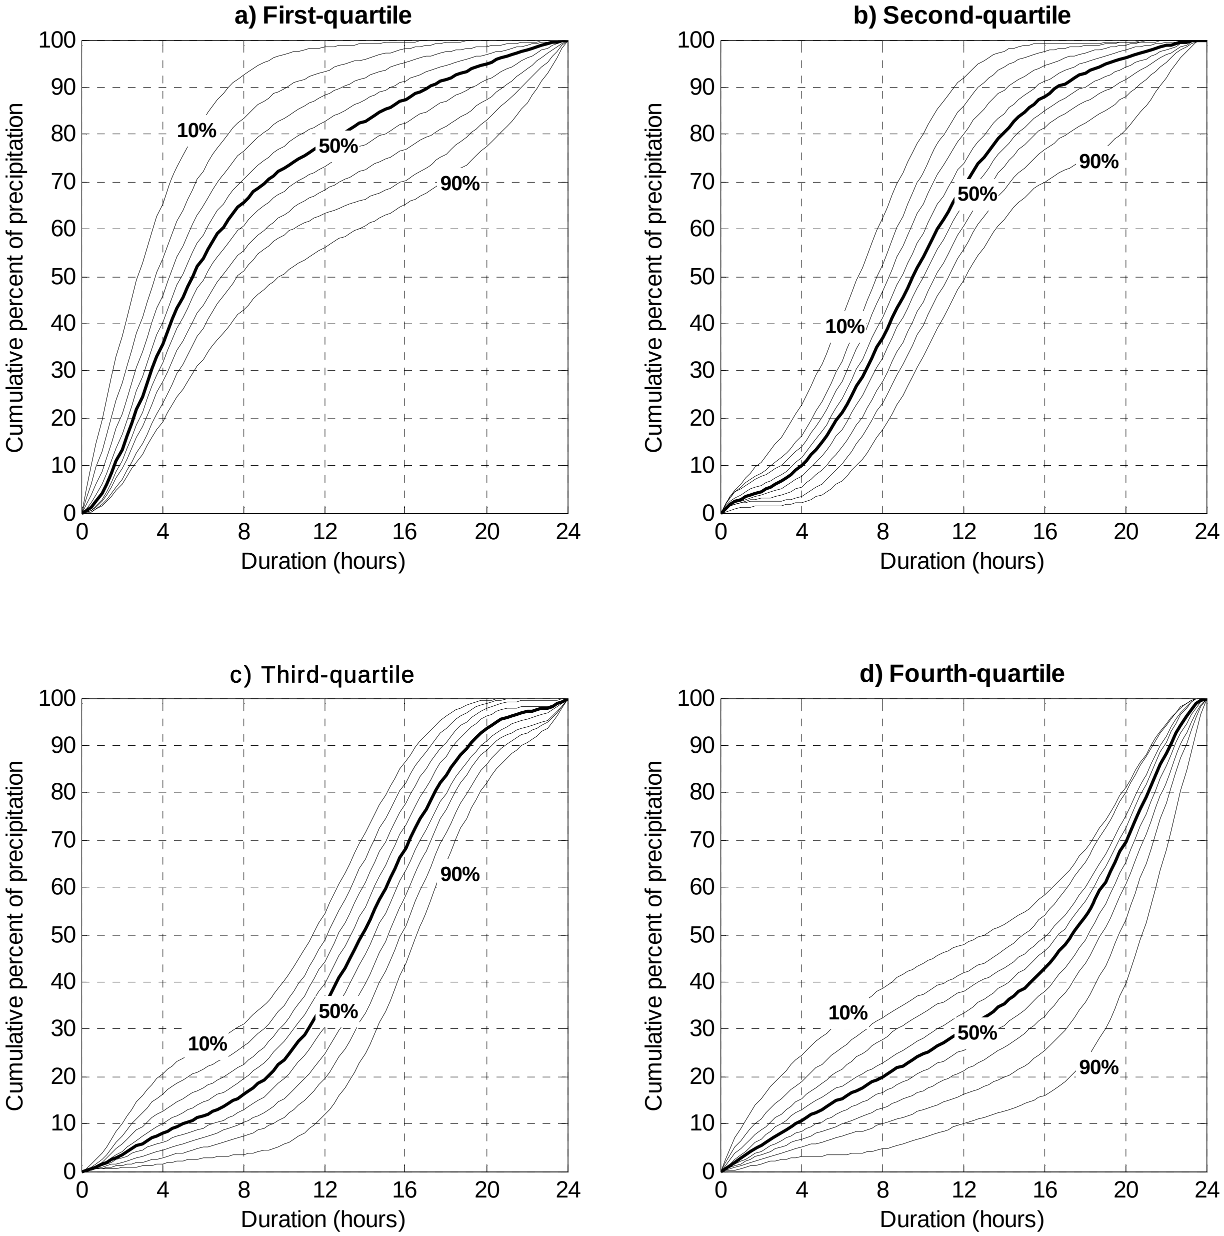

Figure A.8.4. 24-hour temporal distribution curves for: a) first-quartile, b) second-quartile, c) third-quartile, and d) fourth-quartile cases.

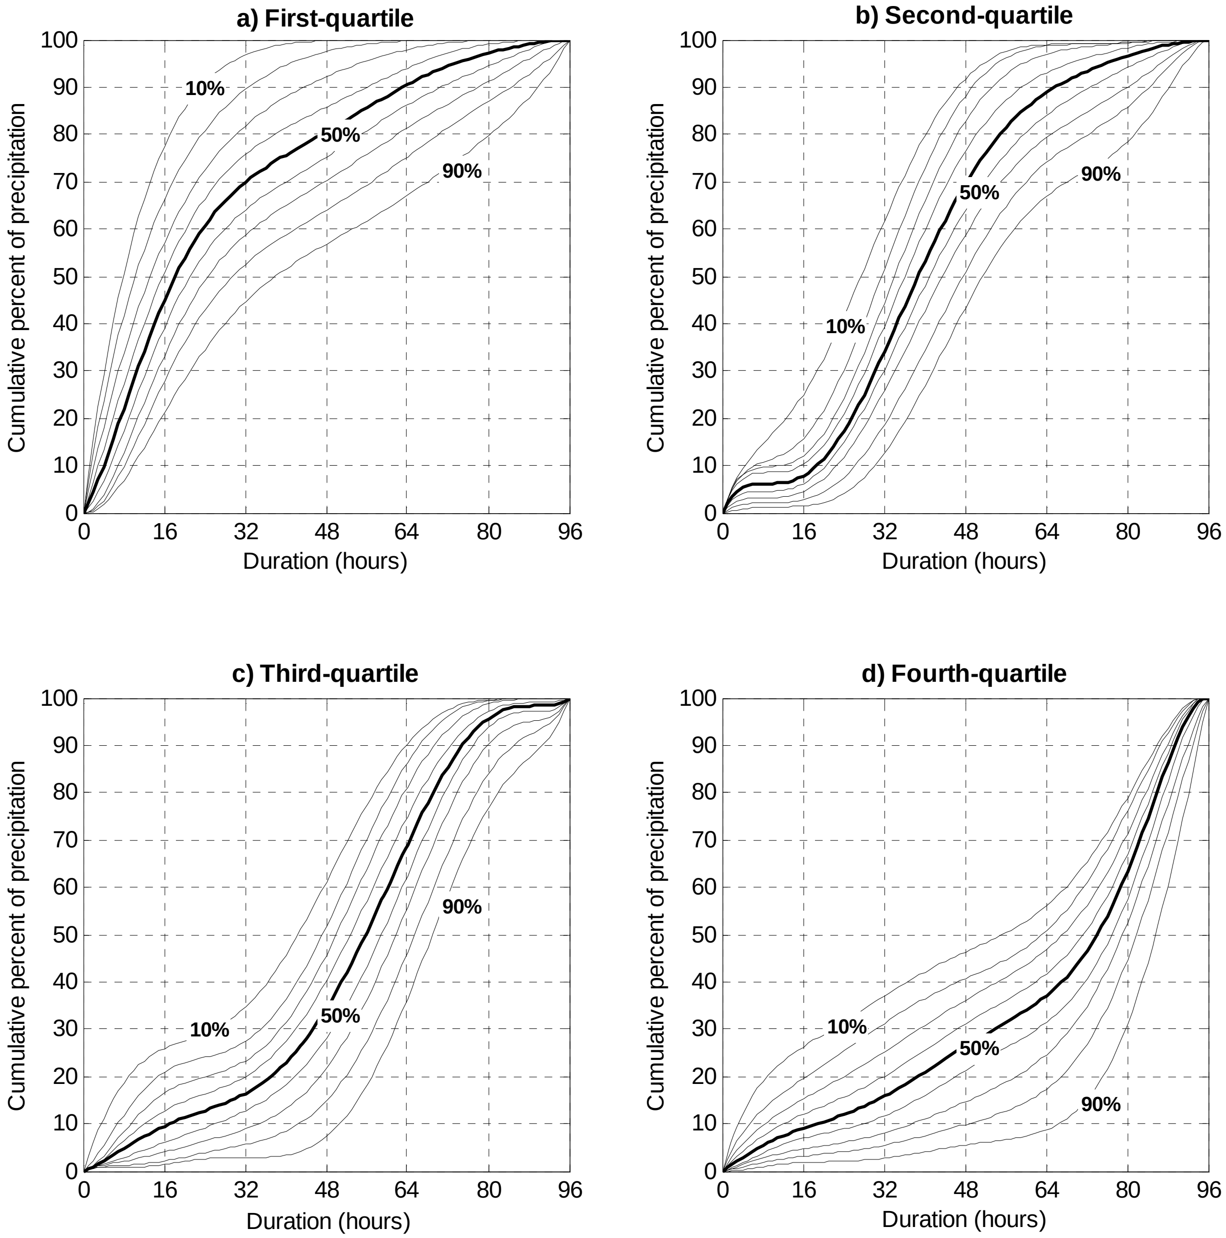

Figure A.8.5. 96-hour temporal distribution curves for: a) first-quartile, b) second-quartile, c) third-quartile, and d) fourth-quartile cases.

Appendix A.9 Seasonality

1. Introduction

To portray the seasonality of extreme precipitation throughout the project area, precipitation amounts that exceeded precipitation frequency estimates (quantiles) with selected annual exceedance probabilities (AEPs) for chosen durations were examined for each region delineated for frequency analysis (shown in Figure 4.5.1). Graphs showing the monthly variation of the exceedances for a region are provided for each location in the project area via the Precipitation Frequency Data Server (PFDS) at http://hdsc.nws.noaa.gov/hdsc/pfds/. For a selected location, seasonal exceedance graphs can be viewed by selecting 'V. Seasonality analysis' of the 'Supplementary information' tab on the output page.

2. Method

Exceedance graphs show the percentage of precipitation totals for a given duration from all stations in a region that exceeded corresponding precipitation frequency estimates at selected AEP levels in each month. Results are provided for unconstrained 60-minute, 24-hour, 2-day, and 10-day durations and for annual exceedance probabilities of 1/2, 1/5, 1/10, 1/25, 1/50, and 1/100.

To prepare the graphs, first, the number of precipitation totals exceeding the precipitation frequency estimate at a station for a given AEP was tabulated for each duration. Those numbers were then combined for all stations in a given region, sorted by month, normalized by the total number of data years in the region, and finally plotted via the PFDS.

3. Results

The exceedance graphs for a selected location (see Figure A.9.1 for an example) indicate percent of annual maxima exceeding the quantiles with selected AEPs for various durations. The percentages are based on regional statistics. On average, 1 % of annual maxima for a given duration in a year (i.e., the sum of percentages of all twelve months) are expected to exceed the 1/100 AEP quantile, 4% is expected to exceed the 1/25 AEP quantile, etc.

Note that seasonality graphs should not be used to derive seasonal precipitation frequency estimates.

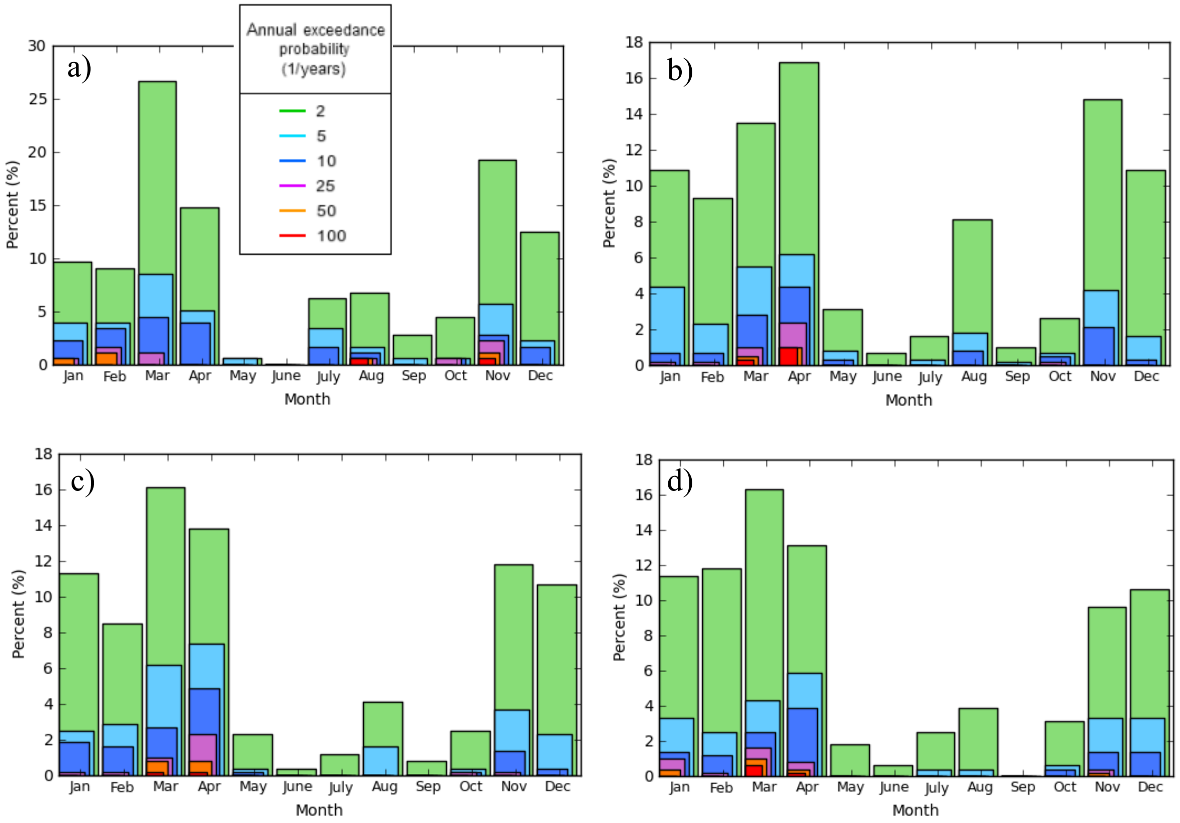

Figure A.9.1. Example of seasonal exceedance graphs for the: a) 60-minute, b) 24-hour, c) 2-day, and d) 10-day durations.

Appendix A.10 Update to Version 3.0

SUMMARY

The NOAA Atlas 14 Volume 4 Version 3.0 update reflects minor adjustments made to precipitation frequency estimates for the sub-hourly (n-minute) durations and updated temporal distribution information. Minor changes to the text were also made, in particular to reflect the updated web pages and functionality of the Precipitation Frequency Data Server. Version 3.0 information supersedes Version 2.1 information.

UPDATES

1. Precipitation frequency estimates at sub-hourly durations

The scaling factors used to produce estimates for n-minute durations from 60-minute estimates were corrected. The updates to the scaling factors are shown in Table 1.1.

Table 1.1. Scaling factors for NOAA Atlas 14 Volume 4 Versions 2.1 and 3.0.

Duration (minutes)	**5**	**10**	**15**	**30**
Scaling factors for Version 2.1	0.27	0.37	0.47	0.69
Scaling factors for Version 3.0	0.29	0.43	0.54	0.76

2. Temporal distributions

Temporal distributions were recalculated using only annual maxima with less than 50% chance of being exceeded in any year. This screened smaller, less relevant cases. Additionally, the criterion which required that no continuous dry period last for more than 30% of the duration was removed from the definition of suitable cases for analysis. The reasoning behind this was that precipitation cases for frequency analysis do not represent a single storm, but may contain parts of one or more storms. More details on the analysis can be found in Appendix A.8.

3. Documentation

The following changes were made in the documentation:

- Sections related to precipitation frequency estimates at sub-hourly durations (Section 4.5.3) and temporal distributions (Appendix A.8) were updated to reflect the above changes.
- The order of appendices was changed to match format of Volumes 5 and 6.
- Section 5 of the documentation which describes the web interface for the Precipitation Frequency Data Server (http://hdsc.nws.noaa.gov/hdsc/pfds/index.html) was revised to reflect the updated web pages and functionality.

Glossary

(All definitions are given relative to precipitation frequency analyses in NOAA Atlas 14 Volume 4)

ANNUAL EXCEEDANCE PROBABILITY (AEP) – The probability associated with exceeding a given amount in any given year once or more than once; the inverse of AEP provides a measure of the average time between years (and not events) in which a particular value is exceeded at least once; the term is associated with analysis of annual maximum series (see also AVERAGE RECCURENCE INTERVAL).

ANNUAL MAXIMUM SERIES (AMS) – Time series of the largest precipitation amounts in a continuous 12-month period (calendar or water year) for a specified duration at a given station.

ASCII GRID – Grid format with a 6-line header, which provides location and size of the grid and precedes the actual grid data. The grid is written as a series of rows, which contain one ASCII integer or floating point value per column in the grid. The first element of the grid corresponds to the upper-left corner of the grid.

AVERAGE RECURRENCE INTERVAL (ARI; a.k.a. RETURN PERIOD, AVERAGE RETURN PERIOD) – Average time between *cases of a particular precipitation magnitude* for a specified duration and at a given location; the term is associated with the analysis of partial duration series. However, ARI is frequently calculated as the inverse of AEP for the annual maximum series; in this case it represents the average period between years in which a given precipitation magnitude is exceeded at least once.

CONSTRAINED OBSERVATION – A precipitation measurement or observation bound by clock hours and occurring in regular intervals. This observation requires conversion to an unconstrained value (see UNCONSTRAINED OBSERVATION) because maximum 60-minute or 24-hour amounts seldom fall within a single hourly or daily observation period.

DATA YEARS – See RECORD LENGTH.

DEPTH-DURATION-FREQUENCY (DDF) CURVE – Graphical depiction of precipitation frequency estimates in terms of depth, duration and frequency (ARI or AEP).

DISCORDANCY MEASURE – Measure used for data quality control and to determine if a station is consistent with other stations in a region. It is calculated for each station in a region as the distance of a point in a 3-dimensional space represented by at-site estimates of three L-moment ratios (L-CV, L-skewness, and L-kurtosis) from the cluster center that is defined using the unweighted average of the three L-moment ratios from all stations within the region.

DISTRIBUTION FUNCTION (CUMULATIVE DISTRIBUTION FUNCTION) – Mathematical description that completely describes frequency distribution of a random variable, here precipitation. Distribution functions commonly used to describe precipitation data include 3-parameter distributions such as Generalized Extreme Value (GEV), Generalized Normal (GNO), Generalized Pareto (GPA), Generalized Logistic (GLO) and Pearson type III (PE3), the 4-parameter Kappa (KAP) distribution, and the 5-parameter Wakeby (WAK) distribution.

FEDERAL GEOGRAPHIC DATA COMMITTEE (FGDC) COMPLIANT METADATA – A document that describes the content, quality, condition, and other characteristics of data and follows the guidelines set forth by the FGDC; metadata is “data about data.”

FREQUENCY – General term for specifying the average recurrence interval or annual exceedance probability associated with specific precipitation magnitude for a given duration.

FREQUENCY ANALYSIS – Process of derivation of a mathematical model that represents the relationship between precipitation magnitudes and their frequencies.

FREQUENCY ESTIMATE – Precipitation magnitude associated with specific average recurrence interval or annual exceedance probability for a given duration.

HETEROGENEITY MEASURE, H1 – Measure that is used to assess regional homogeneity, or lack thereof. It is based on comparison of the variability of sample estimates of coefficient of L-variation in a region relative to their expected variability obtained through simulations.

INDEX-FLOOD – The mean of the annual maximum series at each observing station.

INDEX-FLOOD REGIONAL FREQUENCY ANALYSIS - Regional frequency analysis approach that assumes that all stations in a homogeneous region have a common regional growth curve that becomes station-specific after scaling by a station-specific index flood value. The name comes from its first applications in flood frequency analysis but the method is applicable to precipitation or any other kind of data.

INTENSITY-DURATION-FREQUENCY (IDF) CURVE – Graphical depiction of precipitation frequency estimates in terms of intensity, duration and frequency.

INTERNAL CONSISTENCY – Term used to describe the required behavior of the precipitation frequency estimates from one duration to the next or from one frequency to the next. For instance, it is required that the 100-year 3-hour precipitation frequency estimates be greater than (or at least equal to) corresponding 100-year 2-hour estimates.

L-MOMENTS – L-moments are summary statistics for probability distributions and data samples. They are analogous to ordinary moments, providing measures of location, dispersion, skewness, kurtosis, and other aspects of the shape of probability distributions or data samples, but are computed from linear combinations of the ordered data values (hence the prefix L).

MEAN ANNUAL PRECIPITATION (MAP) – The average precipitation for a year (usually calendar) based on the whole period of record or for a selected period (usually 30 year period such as 1971-2000).

PARTIAL DURATION SERIES (PDS) – Time series that includes all precipitation amounts for a specified duration at a given station above a pre-defined threshold regardless of year; it can include more than one event in any particular year.

PRECIPITATION FREQUENCY DATA SERVER (PFDS) – The on-line portal for all NOAA Atlas 14 deliverables, documentation, and information; http://hdsc.nws.noaa.gov/hdsc/pfds/.

PARAMETER-ELEVATION REGRESSIONS ON INDEPENDENT SLOPES MODEL (PRISM) – Hybrid statistical-geographic approach to mapping climate data developed by Oregon State University's PRISM Climate Group.

QUANTILE – Generic term to indicate the precipitation frequency estimate associated with either ARI or AEP.

RECORD LENGTH – Number of years in which enough precipitation data existed to extract meaningful annual maxima in a station's period of record (or data years).

REGIONAL GROWTH FACTOR (RGF) – A quantile of a regional dimensionless distribution (regional growth curve) that becomes a location-specific precipitation quantile after scaling by a location-specific index-flood. For a given frequency and duration, there is a single RGF for each region.

UNCONSTRAINED OBSERVATION – A precipitation measurement or observation for a defined duration. However the observation is not made at a specific repeating time, rather the duration is a moveable window through time.

WATER YEAR – Any 12-month period, usually selected to begin and end during a relatively dry season. In NOAA Atlas 14 Volume 4, it is defined as the period from October 1 to September 30.
